Don't take a chance on labelled compounds

Don't take a chance on finding the right labelled compound. We make a range of over 1500; you can bet one of them's made for you.

You needn't take chances with purity, either. Our manufacturing, Quality and Stock Control remove the risk of disappointment.

For special products, our custom synthesis and labelling services make sure you get exactly the compound you need.

Don't gamble on delivery. We deliver to most parts of the world in a couple of days. We work through local distributors who

also act as our technical representatives.

Don't take risks with service.

Our technical staff are on call whenever you need help. They regularly visit most parts of the world, and you can rely on them for information and advice.

We publish general interest reviews and technical bulletins. All are free on request.

Finally, here's your chance to try us. Write to us or 'phone. We'll send you our catalogue, the relevant literature and the name of your local agent.

Rp390

make sure the label's ours

Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, $\exp(a)$ is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings to be in Indian ink on heavy cartridge paper, tracing paper or similar materials: thin, shiny, torn or folded material should be avoided. Scales for graphs should be chosen such that simple figures will not occupy an inordinate amount of space. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text they should contain only essential material. Ideally, an unlabelled original and a labelled copy should be provided: labelling on photographs should, if possible, be avoided entirely. Records, charts etc. which will not reproduce well should be redrawn or simply described in the text. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238; 1973)

Haemopoietic stem cells are organised for use on the basis of their generation-age	M. Rosendaal, G. S. Hodgson and T. R. Bradley	68

WE published a brief statement of *Nature's* editorial procedures on page 1 of the issue of November 6, 1975 in the hope that it would help readers and authors to understand how we reach decisions. We also promised to update the statement annually. A year later we have to report that our editorial practice is not substantially different. We would however like to use the opportunity to take up some general points concerning the style of *Nature* papers.

Clear and concise writing is particularly desirable as about 40% of *Nature's* readers know English only as a second language; ambiguity creeps into scientific papers with the greatest of ease.

Because Letters to Nature do not carry an abstract, the first paragraph (of up to 150 words) should be a clear narrative account of the background to the study, the aims of the experiments reported and conclusions that can be drawn. Even one sentence that puts the conclusions in a broader context may be helpful. The first paragraph should be the one that persuades readers that it is worthwhile to read the whole paper.

It is helpful for authors to have it clearly in their minds whether they are writing a 1,000-word letter or a 3,000-word article (see the Guide to Authors on the preceding page). Papers submitted at a length half-way between the two sometimes cause editorial problems.

Multiple references can often be avoided by reference to one review paper.

All papers are seen by a sub-editor before being sent to the typesetter. If there are a large number of queries, the sub-editor will probably correspond directly with the author before the paper is set in type.

Di- and trimethylated congeners of 7-methylguanine in Sindbis virus mRNA	<i>C.-C. H. Chen and D. T. Dubin</i>	190

Interaction of heterocellular hereditary persistence of foetal haemoglobin with β -thalassaemia and sickle cell anaemia	<i>W. G. Wood, D. J. Weatherall and J. B. Clegg</i>	247
Chromosome 21 does not code for an interferon receptor	<i>E. D. Clercq, V. G. Edy and J.-J. Cassiman</i>	249
Episome-like behaviour of donor DNA in transformed strains of <i>Neurospora crassa</i>	<i>N. C. Mishra</i>	251
Genetic polymorphism of C4 in man and localisation of a structural C4 locus to the HLA gene complex of chromosome 6	<i>P. Teisberg, I. Åkesson, B. Olaisen, T. Gedde-Dahl, Jr and E. Thorsby</i>	253
Persistence of anti-immunoglobulin on the lymphocyte surface	<i>A. A. Nash and N. R. Ling</i>	255
Immunodepression, high IgM levels and evasion of the immune response in murine trypanosomiasis	<i>K. M. Hudson, C. Byner, J. Freeman and R. J. Terry</i>	256

Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, *exp (a)* is preferred to *e^a* if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings to be in Indian ink on heavy cartridge paper, tracing paper or similar materials: thin, shiny, torn or folded material should be avoided. Scales for graphs should be chosen such that simple figures will not occupy an inordinate amount of space. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text they should contain only essential material. Ideally, an unlabelled original and a labelled copy should be provided: labelling on photographs should, if possible, be avoided entirely. Records, charts etc. which will not reproduce well should be redrawn or simply described in the text. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Guide to authors

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted, it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, $\exp(a)$ is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors,

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use of the cover, but cannot guarantee its return.

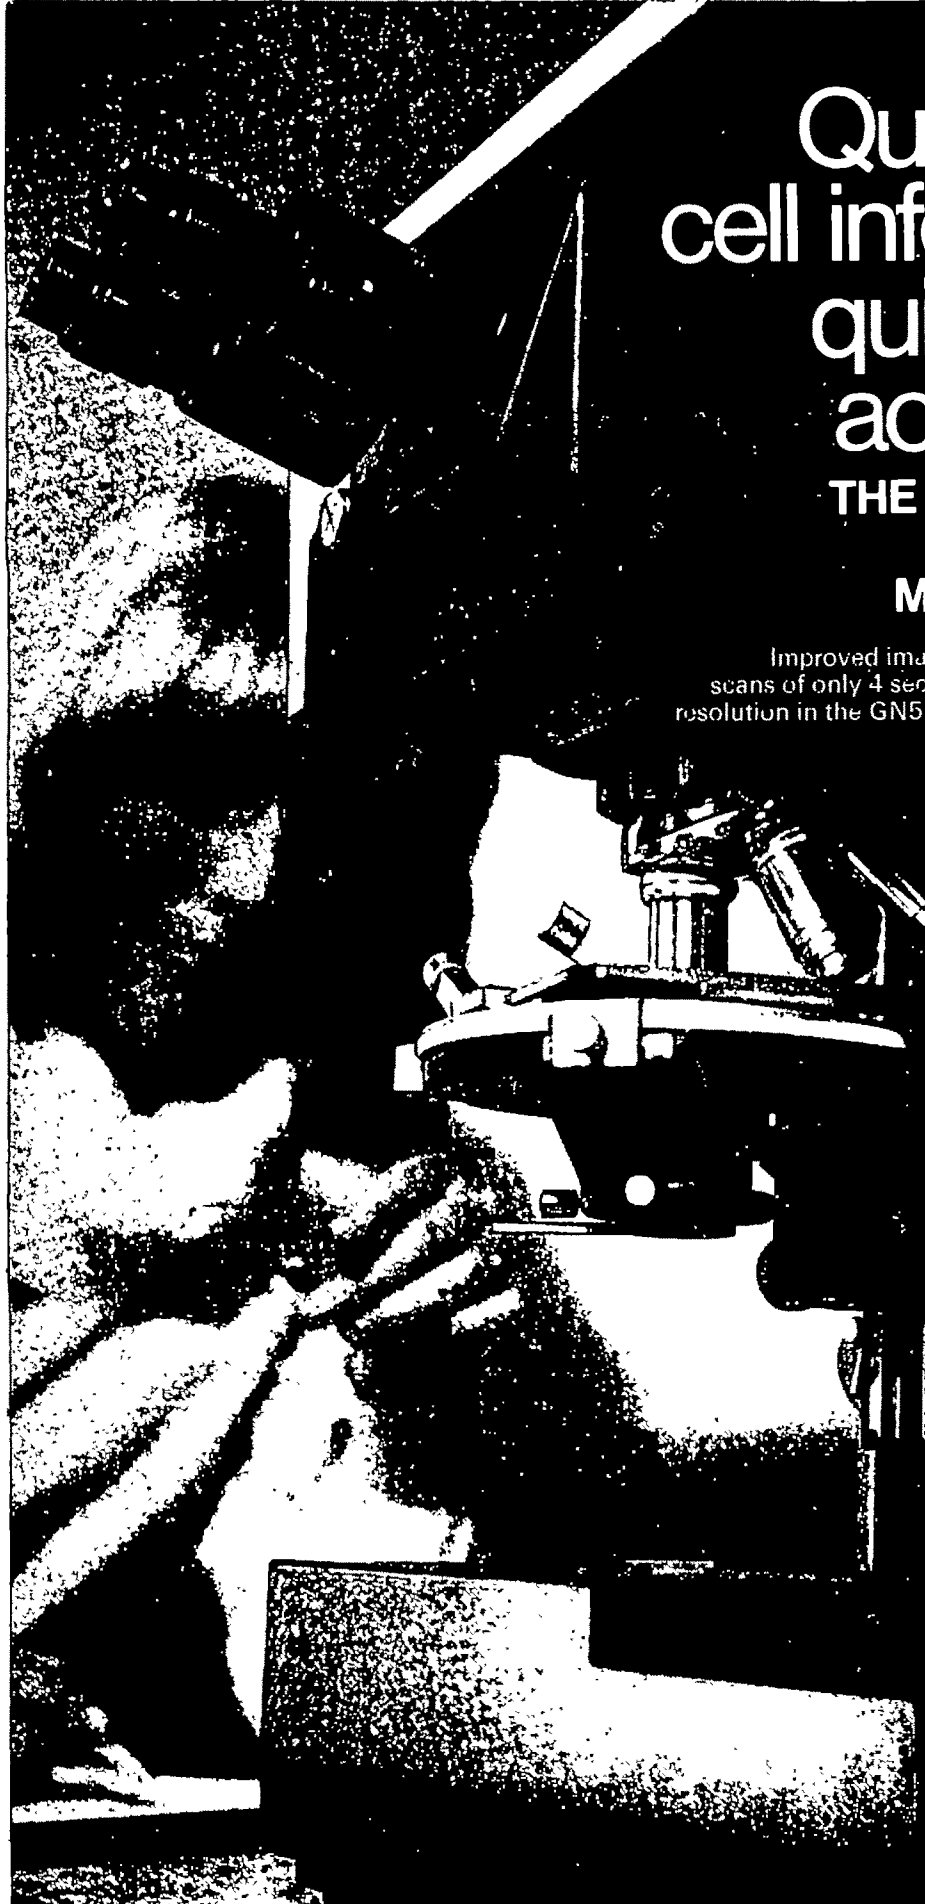

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in 258, 1 (1975) and 264, v (1976)

Monitoring the marine environment for mutagens	J. M. Parry, D. J. Tweats and M. A. J. Al-Mossawi	538
Species richness and stability of space-limited communities	P. Yodzis	540
Effects of drought on grain growth	J. N. Gallagher, P. V. Biscoe and B. Hunter	541
Predicting the course of Gompertzian growth	L. Norton, R. Simon, H. D. Brereton and A. E. Bogden	542
Significance of cell shape in tissue architecture	T. D. Allen and C. S. Potten	545
Transformation of tissue-cultured <i>Xeroderma pigmentosum</i> fibroblasts by treatment with N-methyl-N'-nitro-N-nitrosoguanidine	H. Shimada, H. Shibuta and M. Yoshikawa	547
Distribution and valency of receptor for IgE on rodent mast cells and related tumour cells	G. Mendoza and H. Metzger	548
Lateral motion and valence of Fc receptors on rat peritoneal mast cells	J. Schlessinger, W. W. Webb, E. L. Elson and H. Metzger	550
Induction of an IgM anti-(bovine)-IgG response in mice by bacterial lipopolysaccharide	D. W. Dresser and A. M. Popham	552

Ends of bacteriophage Mu DNA	A. I. Bukhari, S. Froshauer, and M. Botchan	580
Photoformation of polychlorinated biphenyls from chlorinated benzenes	M. Uyeta, S. Taue, K. Chikawa and M. Mazaki	583

CHRISTMAS BOOKS

Colour, song and movement — a selection of books on birds	Peter Conder	585
Spirit of Nature needs rekindling — recent popular books on animal social behaviour	Marlan Dawkins	586

Quantitative cell information quickly and accurately:

THE BARR & STROUD GN5 Integrating Microdensitometer

Improved image analysis techniques give fast scans of only 4 seconds duration with 0.25 micron resolution in the GN5 Integrating Microdensitometer.

For accurate histochemical and cytochemical studies of your cell preparations this new instrument offers an accuracy better than $\pm 1\%$

over an optical density range from less than 0.1 to greater than 2.5.

Area measurement, electronic masking and narrowband illumination are some of the features which make this instrument particularly suited to your laboratory.

The Barr & Stroud GN5 gives quantitative cell information fast and accurately. It is compact, reliable and ergonomically designed for easy operation.

Write or phone for our fully illustrated brochure, publication H-1734.

**BARR AND
STROUD**

The issue of *Nature* published on December 23 will be a double issue dated December 23/30. The next issue after that will be published on January 6, 1977.

There will be two book supplements in the Spring of 1977. Our usual Spring Book Supplement will be published on April 28, and on March 3 we will be publishing an extensive review of recent student books.

We shall continue throughout 1977 to publish a bi-monthly author index in addition to our more comprehensive annual index. The author index is generally included in the first issue of a new volume.

Binders for *Nature* are available at £2.50 each (UK) or US\$5.00 (Rest of World). Four binders will hold a year's copies and cost £8 or \$16.00. Orders should be sent, with remittance, to Nature Circulation Department, Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire.

Capturing the secrets of Nature — natural history for the young	<i>Peter Newmark</i>	587
Nature on the seashore—a collection of books for the beach	<i>J. H. S. Blaxter</i>	587
The Shell Collector's Guide: An Introduction to the World of Shells (S. P. Dance)	<i>T. E. Thompson</i>	588
Bright Wings of Summer: Watching Butterflies (D. G. Measures)	<i>Cyril A. Clarke</i>	589
Jumbo (W. P. Jolly)	<i>R. J. Wheeler</i>	589
Field Photography: Beginning and Advanced Techniques (Alfred A. Blaker)	<i>John B. Free</i>	590
Volcanoes (Peter Francis; A. and L. Rittmann)	<i>Allan Piper</i>	591
Astronomy for the amateur—books for the star-gazer	<i>David W. Hughes</i>	591
The Life that Lives on Man (Michael Andrews)	<i>Kenneth Mellanby</i>	592
Triumphs of Medicine (H. Keen and J. Jarrett)	<i>Tony Smith</i>	593
Islam and the Arab World (Bernard Lewis, editor)	<i>Subir K. Banerjee</i>	594

Reader Enquiry Service

xxxiv

Erratum—just before going to press we noticed that on page 529, in the list of authors, the name of D. C. Soreide had erroneously been included twice. The last author's name in the list of contributors from the Clarendon Laboratory, Oxford, should read D. N. Stacey.

The Index for 1975 is now available. Price £2.25 or US\$5.00, post paid. Cash with order, please, to Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire.

Gallenkamp

Modular

Fermenter flexibility

The new Gallenkamp Modular Fermenter has been designed with the necessary flexibility to suit student

from the simplest batch culture assembly to a fully instrumented continuous fermenter. We have even made

projects, and research and pilot studies on a practical scale

provision for autoclave sterilisation in a compact single unit.

It comprises discrete modules, each controlling only one fermentation parameter. All the modules offer you excellent value. Modules may be combined to form a wide range of systems,

With the modular approach, the fermenter can be assembled to meet your immediate needs and can be adapted for changing longer term requirements. This is what Gallenkamp mean by Modular Fermenter 'flexibility'

Guide to authors

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; $\exp(a)$ is preferred to e^a if ' a ' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors,

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely.

Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use of the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in 258, 1 (1975) and 264, v (1976).

Guide to authors

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures.

Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; $\exp(a)$ is preferred to e^a if ' a ' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors,

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use of the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in 258, 1 (1975) and 264, v (1976).

This issue of *Nature* is a double issue dated December 23/30. The next issue will be published on January 6, 1977.

There will be two book supplements in the Spring of 1977. Our usual Spring Book Supplement will be published on April 28, and on March 3 we will be publishing an extensive review of recent student books.

We shall continue throughout 1977 to publish a bi-monthly author index in addition to our more comprehensive annual index. The author index is generally included in the first issue of a new volume.

Binders for *Nature* are available at £2.50 each (UK) or US\$5.00 (Rest of World). Four binders will hold a year's copies and cost £8 or \$16.00. Orders should be sent, with remittance, to Nature Circulation Department, Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire.

INTRODUCTION TO GEOLOGY:

Volume 2 EARTH HISTORY

**H.H. Read
& Janet Watson**

Part 1 EARLY STAGES OF
EARTH HISTORY

Part 2 LATER STAGES OF
EARTH HISTORY

This scholarly work by two acknowledged experts consists of two parts which together provide a comprehensive outline of earth history covering the whole of the geological time span as well as every continent. Part 1 carries the record to late Precambrian times, Part 2 covers the last thousand million years.

The authors have integrated the records of events that took place at or near the earth's surface with those of tectonic, metamorphic and magmatic events occurring at depth in the crust. The development of large geological units such as mobile belts and basins of deposition are emphasised. Local details are presented where appropriate in relation to the evolution of these units. Economic deposits are discussed in the same context.

The treatment of earth history is based on the concept of a long-term rhythm in the mobility of the earth's crust. The principal divisions of the two Parts deal with successive repetitions of this crustal rhythm, while individual chapters are arranged on a regional basis.

This is the second volume of *Introduction to Geology*. Volume 1, *Principles*, was first published in 1962, with a revised second edition in 1968.

Volume 2

Part 1 hardcover £5 95, paperback £2 95
Part 2 hardcover £6 95, paperback £3 95

Is it taking a liberty?

THE number of lectures and conferences devoted to it is growing all the time. Barely a day passes when there isn't some discussion of it on radio or television or in the newspapers. The subject is the "nuclear issue", and the immediate reason is the decision, due now but delayed a few months, on whether to go ahead in Britain with a demonstration commercial fast breeder reactor. The Minister responsible, Mr Anthony Wedgwood Benn, called for a public debate, and he's getting it. That there might be no "answer" seems to be distracting no one from the search.

The latest contribution comes in a joint publication from Friends of the Earth, the Council for the Protection of Rural England and the National Council of Civil Liberties called *Nuclear Prospects*. Subtitled "A Comment on the Individual, the State and Nuclear Power", it begins to fill a widening hole in the debate, namely a consideration of the social and political implications of nuclear power. The two authors have written what they call a speculative and highly conjectural paper explicitly with the fast breeder decision in mind.

The authors say a postulated commitment to the fast breeder, involving hundreds of tonnes of plutonium-enriched fuel, thousands of fuel shipments annually and some 100 reactors (50 of them breeders), would pose security problems even more enormous than those already caused by existing threats of theft and sabotage. Any attempt to overcome them would extend vastly the existing system of surveillance, policing and vetting inside the industry, and would provide justification for their further extension outside too. Civil liberties would be so threatened that it might be easier for even the Minister himself not to be answerable to the public.

Equally, their argument goes, electricity authorities wanting sites for nuclear stations could clash with local people who, demanding a say in what happens to land, attract wider anti-nuclear sentiment. That would threaten civil discord through direct action if people were unconvinced of the efficacy of parliamentary scrutiny and suspicious of the independence of the Nuclear Installations Inspectorate. Altogether the possible consequences make nuclear power an issue not to be argued simply at a technical level.

Certain obvious points are to be made in confronting these arguments. The security problems posed now by theft, terrorism, sabotage and bombs—even by existing stocks of plutonium—already raise serious questions about civil liberties. Countries cannot opt out of the risks unilaterally if neighbouring countries are "going plutonium". And the social consequences of an insufficiency of energy could be as dire as any caused through the use of fast breeders.

Nuclear Prospects acknowledges the first two of these points, quickly (perhaps too quickly) disposing of them. The authors wonder if civil society would adapt to standards of military security for the benefits of plutonium-based power; perhaps it might. They contend that there is "a world of difference" between exceptional precautions to combat terrorism and the steady erosion of rights threatened by the day-to-day use of plutonium; perhaps there is. But they barely address themselves to the third point, the very one that makes the first two interesting at all.

This may be because there isn't much discussion generally of the matter. Certainly if there is now any received truth in the "great debate" it is the premise that the need for energy will increase and go on increasing in a way that makes the fast breeder decision a decision that must be taken and taken soon. Voluminous documentary support exists for that view, and it cuts little ice at the moment to say that since 1971 no generating plant has been ordered (the companies concerned are reeling) because of simultaneous and seemingly unending inflation and recession.

But consider. Britain, some say, is suffering a long term decline to a subservient neocolonial status in Europe and the West; if so, her predicted energy problems (though not perhaps the world's) could arise even further into the future than presently projected. That is more grist to the mill of those already looking to a comparably financed effort in energy conservation and such alternatives as wave and solar energy to tide them over to a day when fusion or hydrogen might offer inexhaustible supplies of energy. These people imagine a nuclear interlude for Britain, not a nuclear future. Is this really a fantasy? The matter needs more discussion, not just by scientists; it cannot be divorced from a discussion of Britain's future when the cost is so gargantuan.

For consider again. Even those who acknowledge, in strictly energy terms and not with an eye to Britain's electricity industry, the need for a fast breeder, recognise that because of the resources involved the project could only succeed through international collaboration. For Britain, that means with either the French and Germans or with the Americans. The question of who will have her, assuming she can even afford to buy in, is not being discussed in public. But it makes a big difference to the value of any mere internal debate.

Perhaps it is unfair to criticise *Nuclear Prospects* on points that are beyond its intended brief; it certainly deserves praise for trying to fill a great gap in the debate. Mr Benn's decision is mostly symbolic. The debate is far from ritualistic. □

An open letter to the Health and Safety Executive

Michael Ashburner of the Department of Genetics at the University of Cambridge gives his view on the UK Health and Safety Executive's recent proposals for regulating genetic manipulation experiments

Dear Sirs,

The Health and Safety Executive is, I hope, engaging in that popular sport, kite flying. Worried, perhaps, by the mutant monsters so vividly portrayed on television every Saturday evening in *Dr Who*, you write, in your recent Consultative Document "Compulsory Notification of Proposed Genetic Experiments in the Manipulation of Microorganisms":

No person shall carry on any activity intended to alter or likely to alter the genetic constitution of *any microorganism* unless he has given to the Health and Safety Executive notice, in a form approved by the Executive for the purposes of these Regulations, of his *intention* to carry on that activity (Draft Regulation 2 of the Health and Safety (Genetic Manipulations) Regulations 1976). (my italics).

Two recent UK Government reports, those of the Working Parties chaired by Lord Ashby (Cmnd 5880; January 1975) and Professor Sir Robert Williams (Cmnd 6600; August 1976), have considered the problems posed by the recent advances in molecular biology that make it possible to introduce, in a form in which it may replicate and perhaps be transcribed and translated, DNA from "foreign" organisms (including man) into microbial hosts. Both reports considered that such experiments may lead to great social benefit but that they may be dangerous. In view of the potential dangers of some experiments of this type the Williams' Report drafted a Code of Practice to be adhered to when doing such work. This Code lays down "containment" procedures of varying levels of severity to be used for different types of experiment. In effect this will mean that because of the cost of such facilities, these experiments will be done in relatively few laboratories under the strictest supervision.

As you know, the scientific community (a pompous but useful term) is deeply divided concerning the problems that might arise from the use of these new techniques. However, the

"moderate" view is probably that the recommendations of the Williams Report (and their equivalents in the USA) are reasonable and, until we know more about the reality of the dangers, will have to be lived with. Your draft regulation is, I understand, an attempt to give the Code of Practice legal teeth and to place its administration in the hands of the Health and Safety Executive.

The Advisory Group recommended by Williams would play a subservient role to the Health and Safety Executive, despite the fact that this Group alone would include not only technically competent scientists but also "individuals able to take account of the interests of employees and the general public". A central feature of the Advisory Group is that it would "command the respect of the public as well as of the scientific community". If the advice that such a group gives can be overridden by you it would certainly lose this respect and be weakened as a result. The need for the Advisory Group is not simply, as you imply, so that the scientists would not suffer from "unnecessary delay". It is envisaged as taking on a far more important role, independently referring experimental protocols and serving as a channel by means of which new safety features can quickly reach those most directly concerned, in the laboratory.

Of course a weakness of the Williams report is that scant attention is paid to the problems that arise if such techniques come to be widespread in industry. It would make little sense if academic scientists submitted to an essentially voluntary control and industrial scientists were either not controlled or had to submit to a legal control. Accepting that some form of control is required and that this control applies equally to industry, universities and so on—a by no means universal view—the question is, how best should it be applied? Your answers to this question are your draft regulations. I

wish to point out that these regulations, especially regulation 2, are bad from three points of view.

- You remove the Advisory Group or any similar body from any central role in the dialogue that must exist between those who do the experiments and those who administer the laws under which they are done. With respect, sir, you do not have the standing in the scientific community required for this job.

- Instead of being content with covering just the "genetic engineering" experiments your draft regulation would control the *whole of microbial genetics*. You do this despite the lack of any evidence that such control is required to protect public health and safety. The consequences of wording the regulation in this way are very serious. It would make innovation in this important field of study very difficult indeed. Furthermore, the burden on a scientist communicating with you in advance the protocol of his every experiment, for no obvious reason, would be so great that you would lose the confidence and goodwill of the scientific community. If this were to happen the dangers might be very real since you rely upon this community to draw both real and potential hazards to your attention. Remember that it was the scientists who made possible the "genetic engineering" experiments who brought their concern to public attention (*Nature* 250, 175). If a result of the public debate so actively encouraged by them is that scientists find their day to day activities encumbered with endless red tape, some may be reluctant to speak out quite so publicly in the future—and that could lead to a disaster that any subsequent legal process could do little to remedy. It would be a tragedy if certain types of scientific work were driven "underground" as a consequence of a ridiculous regulation.

- The third reason that the draft regulation 2 is bad is that it is unenforceable. A regulation that cannot be enforced would be evaded, at first perhaps not in ways that would present any danger to health or safety, but

eventually by falling into general disrepute and perhaps being ignored totally. It is unenforceable because you would not be able to assess the mountain of forms that would descend upon you, and you would have grave difficulties in drawing a legal line between micro- and "macroorganisms". To enforce it rigidly would also require you to halt many quite "normal" human activities—for example the examination or treatment of people with X-rays (surely *likely* to alter the genetic constitution of microorganisms to which we are hosts), and the treatment of crops with chemicals (which even if they do not alter the genetic constitution of individual microorganisms will

surely alter the constitution of populations of microorganisms). Finally, it makes a nonsense of the evolutionary process: populations of all microorganisms are continuously changing their genetic constitutions and have been doing so since, quite literally, the origin of life. I fear that no law will stop this vast activity.

It is just not good enough to expect scientists to identify techniques (and organisms?) which may be excluded from regulation because they do not present "any potential hazard". Not only is the range of organisms studied so wide, it is impossible to prove that any human activity is completely safe under any circumstances. Dangerous

activities, on the other hand, can usually be positively identified. Whether you list activities to be excluded from the regulations or just those to be included, the regulations will have to be continuously amended to take the results of research into account.

It would be far more effective to draft the regulations to include only those techniques of *known* danger or which scientists judge to be of potential danger, and actively to involve both the scientific community and others in both the assessment of these dangers and the administration of the law itself.

Yours sincerely,

MICHAEL ASHBURNER

An open reply from the Director of the Executive

John Locke, Director of the Health and Safety Executive, takes up the points in Michael Ashburner's letter

Dear Dr Ashburner,

I am glad to have this opportunity of commenting on the points raised by you.

The Government and the Health and Safety Commission have both accepted what you call the "moderate" view that the recommendations of the Williams Report are reasonable. This means that the carrying out of the techniques described in shorthand as "genetic engineering" should be permitted where they offer prospects of social benefit, provided that adequate steps are taken to protect workers in the laboratories and people outside those laboratories from harm. The Williams Committee recommended that in order to achieve this protection those using these techniques, whether in official laboratories or in universities or in industrial firms, should be required to notify their intentions and to seek the advice of the Advisory Group which is being set up by the Government.

The proposals for Regulations, circulated for comment by the Health and Safety Commission, are intended to establish this requirement to notify. The Commission does not believe that it would be right in a matter of this importance to leave people free to decide whether to abide by the recommendations of the Williams Committee. They believe that everybody should be placed

in the same position of being required to give this notification.

The draft Regulations provide for notification to the Health and Safety Executive because we are a statutory body whereas the Advisory Group will have no statutory status. But I really must protest at the suggestion that the Advisory Group would play a subservient role to the Health and Safety Executive. This is simply not the case. It will be for the Advisory Group to lay down the conditions which need to be observed to enable the experiments to proceed safely. Our aim will be to make sure that the Advisory Group is in fact consulted, and secondly to make sure that its recommendations are followed. Both steps are necessary if workers and the general public are to be adequately protected and this is a responsibility placed upon us by Parliament.

Nothing in the Regulations therefore will remove the Advisory Group from its central role in the dialogue between those who wish to carry out experimentation of this kind and those who are competent to advise on the nature of the precautions which need to be taken.

The main point which you raise is that the proposed Regulations are drawn too widely and would catch many activities which do not present special hazards and which were not

dealt with by the Williams Committee. This is certainly true. But the Williams Committee clearly found it very difficult to produce a precise description of the kind of work which they wanted reported. And it is no good at all saying that scientists shall notify their intention of carrying out certain types of work unless they are told pretty precisely what is to be covered.

We hope that as a result of comments on the proposed Regulations, we may be able to suggest a definition of what is to be notified, which, as you say, will cover all those types of work which could present special hazards and require special controls, and which will not be exposed to some of the kinds of objections raised in your note. I entirely agree that neither we nor the Advisory Group should be subjected to "mountains of forms". On the other hand, I am sure you would agree that we must not devise a definition of what is to be notified which would leave out certain types of work which might prove to present special hazards. It seems to us we must err, if we err at all, on the side of having rather more than we want notified rather than too little.

I hope therefore that all those concerned in this field will help us with devising a definition of the activities to be notified to the Advisory Group and to my Executive which will be sensible, workable, and capable of offering the protection to which workers and the general public are entitled.

Yours faithfully,

J. H. LOCKE

Europe's drought (1)

Under the weather

R. M. Morris and R. A. S. Ratcliffe of the Meteorological Office, Bracknell, discuss recent anomalies of the weather and the general atmospheric circulation

THE drastic reduction in rainfall over much of the British Isles from early 1975 represented a rather sudden acceleration of a trend which began at the end of the 1960s. The average annual England and Wales rainfall for 1971–75 was 826 mm, the lowest mean five-year value since the 1850s. There have, however, been six five-year periods since 1825 with annual averages less than 840 mm, so the recent five-year rainfall may be expected to occur once in about 25 years.

Rainfall in the period May 1975 to August 1976 was exceptionally low—in fact the driest such period in England and Wales since 1727, when records officially began. The rainfall total for this period is provisionally assessed at 760 mm compared with the next lowest value of 809 mm in the eighteenth century. Records are regarded as unreliable before about 1825 and if one excludes years before that date the next driest 16-month period starting in May was in 1933–34 with a total of 900 mm. It is difficult to calculate return periods of such an unusual event, but the standard formula suggests at best a once-in-500-year occurrence.

In England the period 23 June to 8 July, 1976, was also exceptionally warm. Mean daily maxima were some 10 °C above the normal values for the time of year and reached 32 °C in some places. Such an event is also unprecedented over the past 250 years. These high temperatures were partly due to the very dry ground, which meant that a smaller proportion of incoming solar radiation than usual was used for evaporating moisture; more was thus available for heating the ground and hence the atmosphere.

Broader perspective

Despite the severity of dryness in England it is important to view the anomalies in a broader spatial and temporal perspective. The distribution of rainfall over most of Europe for the period October 1975 to July 1976, expressed as a percentage of the long-term average (see map), shows that the area of less than 75% broadly extends southwest from Sweden, across the low countries and France to northern Spain, embracing much of England, Wales, eastern Scotland and also southern Germany. Less than 50% is confined to southern England

and northern France with minimum values near the coast of central southern England. On the other hand above average rainfall has occurred over Norway and extreme northern Scotland probably extending across Iceland, whilst similar or greater excesses are evident over western Russia, the Balkans and southern Italy.

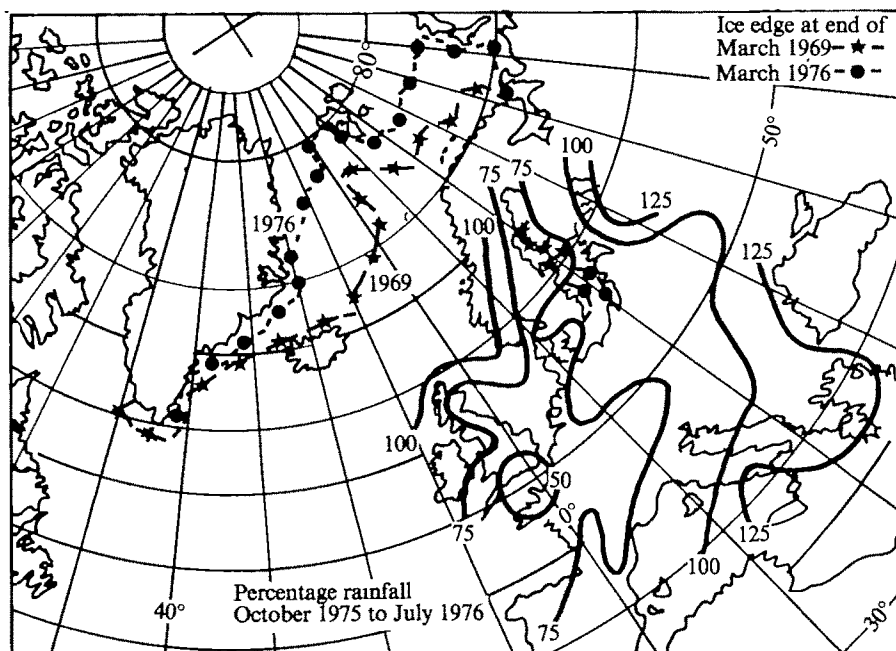

The distribution and evolution of rainfall anomalies on the scale shown is closely linked to the evolution of the major circulation systems in the tropospheric flow around the northern hemisphere. In particular the jetstreams (that is, zones of strong quasi-horizontal wind flow in the middle and upper troposphere) are usually closely associated with the zones of strong thermal contrast which separate regions of markedly different temperature and humidity characteristics. Jetstreams are intrinsically associated with weather because they represent a major cause of the upward and downward motion of the air in the middle layers which produces both extensive cloud systems and cloud-free regions in the circulation. The presence of a jetstream above a certain region usually implies changeable weather, with periods of rain alternating with periods of fine weather. Regions on the cold side of the jetstream (usually the northern side) tend to have a good deal of rain and showers; regions on the warm side tend to have a predominance of dry weather.

Within the past two years the location of the mean jetstream in the Atlantic–European sector of the circulation has shifted almost 1000 miles northwestwards in a coherent and continual manner. The second map illustrates the movement of July–August mean mid-tropospheric jetstream flow from 1974 through 1975 to 1976. Relatively small changes have occurred in the St Lawrence–Newfoundland area and also across the Mediterranean, and a major change has occurred between the northwest European seaboard and Iceland. To put matters in perspective, the mean summer position of the jetstream over the period 1951–70 was close to latitude 50°N across the Atlantic and extended rather weakly to the English Channel. With the jetstream in this position English summers tend to be rather cool and unsettled.

Jetstream shifted

During the winter of 1974–75 the main jetstream across Britain shifted to a position just northwest of the Hebrides. Apart from a temporary falter during the spring it maintained this position throughout most of 1975, moving a little further northwest during November and December. Despite some extremely vigorous cyclonic activity in the northwest Atlantic early in 1976, which actually encroached upon western parts of the British Isles during May, the mean jetstream clung tenaciously to a position between Iceland and Scotland.

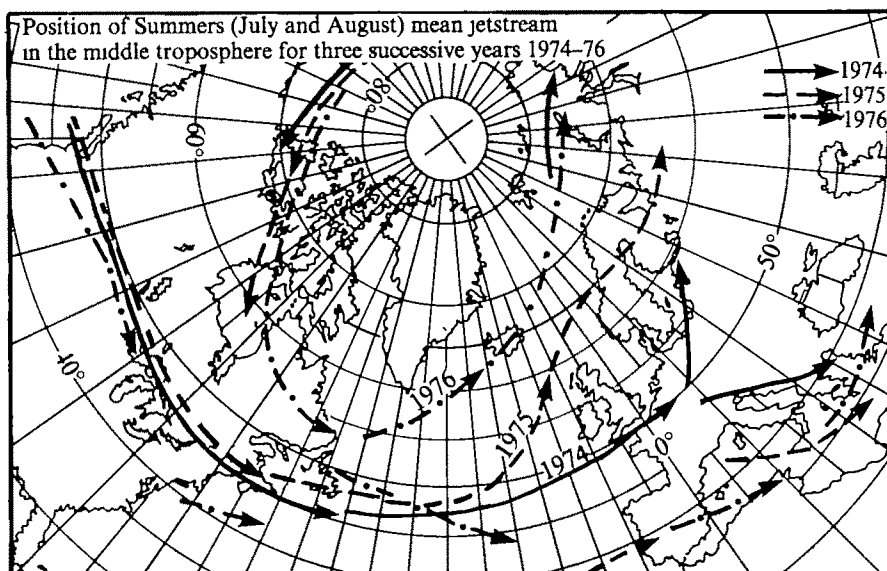

Following the recent summer the jetstream cannot extend further north in view of the proximity of the Arctic ice fields, which will inevitably extend southwards in the winter. The distribution of temperature gradient in the ocean–atmosphere system seems certain

to develop a new jetstream from the eastern USA across the Atlantic towards western Europe, thereby fundamentally changing the situation. Indeed this has already occurred and has been responsible for the recent heavy rain over much of the area worst affected by the drought.

The movement of the mean jetstream flow well to the north of the British Isles was the major cause of the marked reduction in rainfall, and the excesses of rain further north were clearly associated with an increase of jetstream activity not normally present in those latitudes. At the same time the influence of a jetstream upon rainfall anomalies is of limited geographical extent and such is the nature of the circulation that the predominance of cyclonic or anticyclonic regions in a particular region usually leads to the development of anomalous regimes in an adjacent region. The excess rainfall over the eastern and southern fringes of Europe is probably associated with this kind of circulation compensation.

The overall trend during the 1970s has been one of increased cyclonic activity in the Arctic basin, especially across the extreme north Atlantic and

Norwegian Sea, and increased anticyclonic conditions over western Europe. Such a circulation implies more frequent and stronger westerly winds than usual north of about 55° N in our sector. The increased westerly winds and cyclonic activity in the north have been associated with a marked recession northwards of the Arctic ice.

Up to 1969 Arctic ice to the north of Britain was extending southwards and reached its extreme southern position in March 1969 (see map). By March 1976 the area of open water in the Greenland-Spitzbergen area had increased by about 1.4 million square kilometres compared with March 1969. □

Europe's drought (2)

Water everywhere?

Haydon Richards of the Central Water Planning Unit assesses Europe's water resources

WATER is one of the natural resources with which Europe is better endowed than many other large areas of the world. This generalisation does, however, mask variations in geographical distribution of resources as compared with demands. The summer of 1976 has emphasised an extreme of variation. The driest 16-month period on record, from May 1975 to August 1976, has severely tested resources designed to provide a continuous water supply, but on the whole demands have been met and criteria used for design have proved to be sound. If living conditions are to be maintained or improved then demands have to be met for the four main sectors of public water supply, industry, agriculture and thermal power station cooling. The unusual conditions of 1976 have at least emphasised those areas where additional storage of water in some form needs to be made available in order to satisfy these demands and not impose severe restrictions on water use.

Estimating demand

Reasonably accurate estimates of

demand need to be made in order to plan development of suitable resources. Traditionally, trends over a number of years have determined the level of demand to be met at a particular time in the future, but more recent estimates have attempted to break down the components of the total demand. A good deal still remains to be done in this field. Publicity this summer has led to marked lowering of demand for public water supplies and for industry, amounting to at least 20% of normal demand in some areas. However, the knowledge that water is again abundant after a time may well reduce the attitude of care and thus increase demands to "normal" levels.

Apart from the demands to be met from the four major sectors the needs of ecology and amenity have to be borne in mind. Sufficient water must be left in rivers and lakes for aquatic life to continue, effluents to be suitably diluted, navigation to be possible and for fishermen and picnickers to enjoy their leisure. There must therefore be some idea of the quantity to be left in a natural watercourse to prevent un-

acceptable damage to the environment. This quantity can be determined only by agreement between all users of a particular river catchment and the criteria used may differ from one to the other, general amenity perhaps being over-riding in an upland or rural setting and effluent dilution in an industrial area.

Future projections in demand for water until the end of the century suggest high growth rates in excess of 200% in the Netherlands and at least 150% in Luxembourg, whereas in France demands may increase by little more than a quarter. Recent estimates indicate that Germany and the United Kingdom will need to increase use by 60 or 70%. Those countries with a high proportion of agricultural water demands locally, such as France and Italy, may have developed methods of meeting those demands locally, whereas the increased industrial demands in other countries have to be met by providing major new resources at some distance from the centres of demand.

Increasingly, demands for cooling water are being met from saline waters. Italy and Denmark benefit from long coastlines and use only a small proportion of freshwater for cooling in thermal power stations, although thermal pollution then becomes a problem. Some 30% of cooling tower water is evaporated, and this forms a consumptive use of water because it is lost as a resource. In the same way

water used for irrigation is almost totally lost as a water resource. Groundwater is important for meeting demands for potable water because it is usually of good quality, but only in France is it used to supply water for power station cooling. In Denmark, where there are no rivers of any size, nearly all water for public supplies, agriculture and industry is derived from groundwater storage, and in Belgium about three-quarters is so derived; in Ireland very little is used.

Water resources

Water resources are renewed annually from precipitation on the land surface, the effective rainfall being that which remains for surface runoff or infiltration to groundwater storage after evaporation and replenishment of soil moisture deficits.

Calculating average annual renewal of water resources provides an idea of the potential resource available in different countries. Ireland with its moist equable climate has approximately 32,000 litres a day available for each person from effective rainfall, whereas Belgium has about 3,000 litres a day; figures for other countries in north-west Europe lie between these.

The daily per capita consumption for all purposes in 1969 in Belgium was 119 litres and other countries range up to 280 litres. Even allowing for minimum flows to be maintained in rivers, therefore, nature still provides a substantial surplus of water which can be exploited to meet changing or increasing demands. Belgium's fresh water resources are found in three rivers and in extensive aquifers, and from the latter is obtained almost three-quarters of the public water supply. Regarding other European countries:

- On the low-lying Danish peninsula the small streams are fed by natural groundwater discharge. Some surface water is used to supplement the Copenhagen supply, but groundwater supplies nearly all the country's needs apart from thermal power plant cooling.

- Rainfall in France varies from about 850 mm per annum in the west to less than 500 mm near the Mediterranean. Below average snowfall in the Alps last winter slightly reduced some stream-flows during the summer of 1976. There are extensive aquifers in north east France and alluvial aquifers in the major river valleys.

- In West Germany there are also several rainfall zones, from the alpine south with high rain and snowfall, through the central highlands where the average annual rainfall is at least 1,000 mm, to the central lowland with an annual average of 730 mm. The flows of all the main rivers are fairly uniformly distributed throughout the year. Groundwater occurs mainly in the

flat alluvial tracts of the river valleys and beneath the northern plains, and provides well over half the public water supplies.

- Ireland is better endowed with water resources than most other countries in Europe, having a low population density and high rainfall which varies from 2,000 mm per annum on the west coast to little over 600 mm on parts of the east coast. There are several rivers and numerous lakes. Groundwater is widely used to supply farms but this source accounts for only about 7% of the total demand for potable water.

The Rhine is of first importance to water management in the Netherlands and it provides over 60% of the total, including power station cooling; groundwater provides more than a quarter of this total and the remainder is derived from the Meuse and small rivers. Navigation requirements also exercise control over water use because minimum levels have to be maintained to meet international agreements. Any open connection with the sea creates the possibility of an inflow of salt water and so substantial outflows are required in the areas below sea-level in the west of the country. Such control is linked to the general care taken to control salt water seepage into the polder areas. Potential resources from the Rhine are very large, but because of variations in the quality of the water management problems in the Netherlands are complex and involve storage in lakes, artificial recharge of sand dunes and the linking of existing sources.

There are marked geographical variations in rainfall in the United Kingdom; annual variations have been highlighted recently with rainfall in the year to August 1976 only 63% of the long term average over England and Wales. Groundwater provides 35% of public water supplies in England and Wales. Natural groundwater discharge provides 80% or more of the total annual flow of many rivers flowing from or over the major aquifer, the Chalk. Lesser percentages are contributed to streams from other aquifers.

Traditionally in the United Kingdom demands have been met in most areas by direct pipeline supply from upland reservoirs; reservoirs in the lower Thames valley are filled by pumping from the river. Along several rivers in England, water is used, returned as treated effluent and re-used lower down stream, and advances in the technology of water treatment in the last few decades has increased the possibility of using upland storage to regulate the flows of such rivers.

Water management

Both Ireland and Denmark tend to use a water resource and then ensure that the effluent is discharged after suitable

treatment to the sea. Countries with large inland industrial and urban areas such as France, Germany and the United Kingdom are faced with the problems of costly effluent treatment if the environment is to be protected, and particularly if water is to be re-used for further public, industrial or agricultural supply or amenity. In France, as in Italy, there are large numbers of small reservoirs in the hilly areas providing storage for farm irrigation, but this is not common elsewhere. Systems of control over agencies supplying water, managing rivers and dealing with effluent and sewage treatment vary greatly, but most countries have some form of statutory or voluntary means of tackling aspects of water development and use in defined catchments.

Direct supply of water from source to demand area will continue, but study of the relative costs of providing additional resources will probably produce different methods of using some existing sources. Schemes for the combined use of a number of sources can exploit their contrasting temporal characteristics, as for example when a supply from a river during winter is stopped during summer at times of low river flow, the summer supply being obtained by abstraction from groundwater storage which in turn is normally refilled by winter infiltration from rainfall. Such complex operations require suitable systems of data collection relating to quantity and quality of water in storage above and below ground, and the ability to forecast resources in store, changes in demand, operational problems and the likely results of any decision to use resources differently.

In spite of the uneven distribution of rainfall and of resources in rivers, lakes and aquifers there is sufficient water in the countries of north west Europe to satisfy foreseeable demands well into the next century. Care will be needed to ensure correct treatment of effluents, protection of the quality of surface water and groundwater and the maintenance of river flows for navigation and amenity. Additional storage is needed to meet shortages in certain areas, and by and large these have been emphasised during the dry period of the summer of 1976. This year has also shown that many of the major reservoirs have been designed so as to provide a large part of the required supply even through these unusual conditions. Groundwater storage has also helped by allowing abstraction at rates in excess of the long-term average renewal of storage, and the potential for even greater use during another severe dry period should be determined in necessary detail. No doubt methods of influencing demand patterns and modifying demands will be explored and developed. □

POPULATION

Will world population double?

Colin Norman looks at a new analysis of population trends throughout the world which has produced findings that are both encouraging and decidedly grim

THERE has been a dramatic slowdown in world population growth in the past five years as many countries, paced by China and the United States, have brought their birth rates down sharply. But death rates have risen steeply in some poor countries because crop failures and increasing pressure on agricultural resources and fisheries have claimed about two million lives. So says the study* of population trends conducted by Lester Brown and published by the Worldwatch Institute of which he is the President.

It paints a grisly picture of a world living from hand-to-mouth, with virtually no food reserves left to guard against poor harvests or other natural disasters, and with croplands, forests, grasslands and fisheries in many poor, densely populated regions close to breaking point. Brown concludes from the trends that "it's quite possible that we will never again see a doubling in world population growth, in spite of the fact that it is the standard rhetoric of UN officials", because for a great majority of countries, "a doubling of population will yield potentially unmanageable ecological, economic and political stresses".

Brown's principal conclusion is that "sometime near the beginning of this decade, the rate of world population growth reached an all time high and then began to subside". Though the total number of people in the world rose from 3,590 million in 1970 to 3,920 million in 1975, Brown estimates that the annual rate of increase has shrunk from 1.90% to 1.64%, a dramatic and, to some observers, surprising decline.

The bright side of the picture is that birth rates are falling in almost every country as more and more governments are reversing pro-natalist policies and instituting family planning programmes. Four European countries—East Germany, West Germany, Luxembourg and Austria—have already reached zero population growth and two others, Belgium and the United Kingdom, are expected to reach that point sometime this year. But by far the most dramatic reduction has

occurred in China and in some other East Asian countries.

With one-fifth of the world's people, China has a huge influence on overall population trends. According to Brown's estimates, China has just achieved "family planning's greatest success story", reducing the country's birth rate from a crippling 32 per 10,000 in 1970, to a more manageable 19 in 1975. Though hard and fast data for China are difficult to come by, Brown bases his estimate chiefly on figures supported by a variety of sources, on birth and death rates in political units in China, which he extrapolates to the entire population. His estimate for China's population growth is lower than one produced by the US Bureau of the Census a couple of years ago, but higher than a more recent estimate of the Agency for International Development.

But China isn't the only country to show a surprising reduction in its population growth. In some ways, the trend in the United States is equally striking. During the past five years, the growth rate in the US has declined by about a third, from 0.9 to about 0.6%, Brown estimates, in spite of the fact that children of the post-war baby boom have recently entered their prime reproductive years. The reasons include a drop in the marriage rate, increasing employment of women, and increasing female enrolment in graduate and professional schools.

And social trends elsewhere are equally significant. Mexico has recently completely reversed its pro-natalist policy and has instituted a strong family planning effort. And abortion laws have recently been liberalised in many countries, including predominantly Catholic nations such as France. In fact, Brown states that the proportion of the world's people living in countries where abortion is easy to obtain has increased from 38% to 64% in the past five years. "Few social changes have ever swept the world so quickly", he notes.

But in some parts of the world rising death rates have also played a part in reducing population growth. The grimest figures have come from the Indian sub-continent, particularly Bangladesh. Though Brown notes that few national leaders are eager to discuss rising death rates and good data are therefore difficult to obtain, he has pulled together data from a variety of sources which put into perspective the tragic impact of the Bangladesh war of independence from Pakistan and the

failure of the Indian harvest in 1972.

Brown bases his estimates for Bangladesh on meticulous records for death rates in the province of Matlab Bazar, maintained by the International Cholera Research Laboratory. The death rate in that province climbed from 15.3 in 1966-70 period to 21.4 in 1972. If the figure is extrapolated to the entire country, it suggests a nationwide increase in deaths from hunger of 427,000 that year. Similar extrapolations for 1974-75, when Bangladesh's rice crop was poor, suggest that the grim death toll was about 330,000.

Equally distressing figures emerge from extrapolations in India. In 1971 and early 1972, India had fed an estimated 8-10 million refugees from Bangladesh from its own grain reserves, but in late 1972 it was caught by two related disasters. First, the monsoon failed that year, severely reducing India's wheat harvest. And second, that same year, the Soviet Union imported 30 million tons of grain from the United States, thereby tying up most of the world's exportable wheat supplies. Official figures for death rates in India that year show an increase in Uttar Pradesh from 20.1 to 25.6, and equally steep jumps in two other provinces. Brown calculates that "in these three states alone, hunger claimed an estimated 829,000 lives". The figures in the Worldwatch report are the first authoritative estimates of the impact of crop failures on demographic trends in the region.

But Brown argues that death tolls from massive failure of crops and other disasters such as the Sahel drought are only one measure of the impact of overpopulation. Less obvious, but potentially more important is the fact that population growth is "simultaneously contributing to growth in food demand and to reduced food output". Overfishing is depleting fish stocks, he argues, and in many regions, overgrazing, deforestation and overploughing are leading to soil erosion, desert encroachment and the abandonment of crop lands. "It has been evident for some time that oceanic fisheries could collapse under the pressure of excessive demand. What is becoming equally clear is that land-based food systems can also give way under intense pressure", he argues.

For those reasons, he contends that it is difficult to believe that world population will ever double again, simply because few countries are capable of supporting double their present population.

Such realisations are beginning to show up in the implementation of family planning programmes. Nowhere is that development more striking than

**World Population Trends: Signs of Hope, Signs of Stress*, published by the Worldwatch Institute, 1776 Massachusetts Ave NW, Washington DC 20036. \$2.00.

in India, perhaps the nation hardest hit by hunger in the past few years. In the state of Maharashtra, the legislature has approved with only one dissenting voice a bill for compulsory sterilisation

of all males with three or more living children. Even if the measure is never implemented, the fact that such Draconian steps are being discussed is an important indicator of the serious-

ness with which India now regards the population problem. "Five years ago", Brown said last week, "compulsory sterilisation would not have been an acceptable topic for discussion in India".

NUCLEAR TRADE

Ford makes his move

With just five days to go before the Presidential election, Mr Ford last week announced long-awaited proposals designed to prevent countries which import nuclear technology from building atomic bombs. Colin Norman reports from Washington

MR FORD's proposals, which have been extensively leaked during the past few weeks, represent some significant reversals of past Administration policy, and in some respects resemble less detailed suggestions made last May by his Democratic opponent Jimmy Carter. The crux of the new policy, outlined in a lengthy statement released by the White House, is that the United States should back away from its own plans to separate plutonium from spent nuclear fuel and recycle it as a reactor fuel. In addition, Mr Ford offered a raft of proposals for international co-operation in preventing the spread of nuclear weapons, including the following:

- He called upon all countries to refrain from selling reprocessing technology or uranium enrichment plants for at least three years. Already, West Germany has agreed to sell reprocessing and enrichment plants to Brazil, and France is committed to selling a reprocessing plant to Pakistan. Asked last week whether the Administration intends to enforce the policy in respect of those two deals, the Under Secretary of State for Economic Affairs, Charles W. Robinson, hedged by suggesting merely that "I think the statement that has been released by the President will be helpful in pursuing our interests in this matter".

- Mr Ford urged "new co-operative steps . . . to help assure that all nations have an adequate and reliable supply of energy for their needs". To that end he has asked the Secretary of State to initiate discussions with other suppliers to seek arrangements for co-ordinating fuel services. In particular, "these discussions will address ways to ensure against economic disadvantage to co-operating nations and to remove

any sources of competition which would undermine our common non-proliferation efforts". He also announced that the United States should increase its own enrichment capacity, particularly by expanding the government-owned plant at Portsmouth, Ohio. (The statement, it should be noted, was made in Cincinnati, Ohio.)

- Ford also stated that he has asked the Secretary of State to initiate international discussions aimed at establishing a new facility for storing plutonium and spent fuel from civil power stations, under the control of the International Atomic Energy Agency. He also pledged to place excess US plutonium in the facility once it is established.

- As for sanctions to deter nations from acquiring nuclear weapons, Ford stated that "any material violation of a nuclear safeguards agreement . . . must be universally judged to be an extremely serious affront to the world community, calling for the immediate imposition of drastic sanctions". In particular, he promised that the United States will, "at a minimum" respond to violation of any safeguards agreement to which the US is a party with "an immediate cutoff of our supply of nuclear fuel and cooperation to that nation".

In that regard, it should be noted that the atomic device exploded by India in 1974 was made from plutonium produced in a reactor which was moderated by heavy water supplied by the US under an agreement that it be used only for peaceful purposes. Does Mr Ford's threat to cut off fuel supplies therefore apply to India's apparent violation of its safeguards agreement? Mr Robinson would not commit himself last week, noting only that the United States has been negotiating with India to repurchase spent fuel from the Tarapur Atomic Plant, and that those negotiations "will be given new emphasis and support" by Ford's statement.

Asked later whether a second explosion by India would be sufficient to prompt a cutoff in aid, Robinson still refused to be drawn: "That obviously

would be viewed as a very serious matter . . . We must understand, however, that we are going back to an agreement concluded a number of years ago where our present concerns were not fully reflected in the contractual terms".

As for the United States' domestic nuclear programme, Ford said that he would speed up the effort to find a suitable method of disposing of radioactive wastes, and that he is directing the Secretary of State to initiate international discussions on the possibility of establishing centrally located, multinational waste repositories. His most important announcement, however, was that the US nuclear industry should no longer plan on reprocessing wastes and recycling plutonium.

A commercial reprocessing plant is already almost completed in Barnwell, South Carolina, and the nuclear industry has applied for a licence to begin recycling plutonium as a reactor fuel. Ford stated, however, that the United States "should no longer regard the reprocessing of nuclear fuel as a necessary and inevitable step." Reprocessing and recycling, he said, should only be permitted "if they are found to be consistent with our international objectives".

That leaves the Barnwell plant in a peculiar position since a decision to forego reprocessing would make it redundant before it even starts operating. One possibility, however, is that the Energy Research and Development Administration may seek Congressional approval to complete the plant and to operate it on an experimental basis to help evaluate the economics and the technological and safety problems associated with reprocessing. Ford's statement, in fact, said that he hopes to seek international participation in such an evaluation effort.

Finally, it should be noted that Ford's statement made no mention at all of an aspect of nuclear proliferation which many arms control experts see as central to the issue, namely, the controls which the superpowers are willing to place on their own weapons developments, particularly the testing of nuclear weapons. But those are touchy issues, and it was five days before the election. □

SWEDEN

● Less than a week after the formation of Sweden's new three-party government, Prime Minister Thorbjörn Fälldin's election promise to stop the insertion of fuel into the Barsebäck 2 nuclear reactor fell victim to the compromises said to be necessary for the survival of the coalition and insertion was allowed to go ahead. In a declaration of the government's programme, Fälldin said in effect that the government would stop the reactor going into operation unless its owners produce acceptable plans for the reprocessing of spent fuel and proof that radioactive waste will be stored in complete isolation from all life for eternity. The deadline for the presentation of these plans is October 1, 1977.

Politicians opposed to nuclear energy assert that the reactor's owners will not be able to come up with any proposals acceptable to the government. The nuclear industry is confident that it can. The effect is to throw open the entire question of whether the country's reactor plans are to be stopped, or even greatly slowed down: Sweden's construction workers are already seeking assurances about nuclear power stations now being built.

Fälldin also announced the formation of a commission which will evaluate the research done so far on the security and environmental aspects of nuclear power as well as the storage of highly radioactive waste. The commission is also to make suggestions for a new energy policy to be presented to parliament in 1978, until which time it seems that the futures of other reactors under construction will hang fire. It has at least been made clear that the twelfth in the planned series of thirteen reactors will not now be built at all, and this would presumably also apply to the thirteenth.

Meanwhile, in what has been dubbed as Operation Striptease, the findings of the Committee on Radioactive Waste have been attacked by academics and politicians who want to reveal its unwarranted optimism about the long-term storage of spent fuel. Action to endorse the committee's conclusions has come from only one source, a local government council which, amidst lively public debate, has voted to allow reprocessing and storage plants to be built near the Forsmark reactors already in operation.

● The hullabaloo over Barsebäck 2 has overshadowed a surprisingly favourable legal decision recently won

by one anti-nuclear power group. The Supreme Water Court has ordered the State Power Board to lower the level of radioactivity in the cooling water to be discharged from the third and fourth Ringhals reactors. In addition, the Court has directed the Board to pay about US\$22,000 in legal

costs to those who pressed the case, the environmentalist Björn Gillberg and Gunnar Michelson, a lawyer.

Following the Court's decision, the release of tritium must be lowered from 10,000 to 3,700 curies per reactor per year; of isotopes emitting beta and gamma rays, from 100 to 2–24 curies per reactor per year; and of isotopes emitting alpha rays, from 50 to zero curies per reactor per year. As the case of beta and gamma rays suggests, the new figures are not so much absolute limits as indications of what the Court thinks should be feasible, according to what is technically possible and economically reasonable. Its decision allows the Power Board to make very occasional releases of much greater amounts of radioactivity—but only when it may be technically impossible to avoid doing so. Any repeatedly greater releases would be investigated by the National Institute for Radiation Protection and could put the Board back in court for another trial.

Gillberg and Michelson lost that part of their case in which they had argued for a reduction in the volume of cooling water which is to be released into the sea. According to Gillberg, they are thinking of appealing on this issue to the Supreme Court. If they do, they will shore up the Prime Minister's creaking campaign to stop Sweden's nuclear power programme. The reactors' debut (planned for December 1977 and July 1979) would have to be postponed until the appeal had been heard and a judgment made, a process which would probably take two or three years.

● With nuclear fission such a controversial issue, the case for fusion could grow. Bo Lehnert, professor of plasma physics and fusion research at Stockholm's Royal Institute of Technology, says fusion would not involve the two problems normally associated with fission, namely radioactive waste products and reactor accidents; the radioactivity which neutrons would induce in the material surrounding the reaction could be diminished by using vanadium and its alloys in the wall material. He says that even if materials less suitable than these were used, the level of radioactivity and the corresponding biological hazards would be many orders of magnitude smaller than with a corresponding amount of energy produced by fission. Reactor accidents would also be less severe with fusion than with fission, says Lehnert, partly because no runaway nuclear reactions would be possible in an incident involving a fusion reactor.

Fusion power, then, is extremely attractive to the Swedes, as it is in many developed countries, and they have not been idle in their research. Their interest dates from the mid-1950s, Lehnert's group being financed mainly by the Swedish Atomic Research Council and the Bank of Sweden Tercentenary Fund. From 1976, however, it has joined with the team working under Hans Wilhelmsson, professor of electromagnetic field theory at Chalmers Institute of Technology, near Gothenburg, to form a fusion research unit associated with Euratom, which now shares the support of the unit with the Atomic Research Council. The immediate result of this has been a doubling of research funds, which amount this financial year to Skr4 million (about US\$900,000).

Lehnert is, however, dissatisfied with what he considers to be the narrowness of present fusion research. His general, and personal feeling—"controlled optimism for controlled fusion"—cannot give immediate comfort to anyone involved in the debate over fission reactors. Given a frontal attack on a wide variety of problems, including basic research, new ideas and modified old ideas, he believes that commercial fusion reactors may be "not quite unimaginable" before the year 2000. But with research going in current directions at its present level of finance, he forecasts a longer wait.

Wendy Barnaby

IN BRIEF

Ford statement attacked

President Ford was given a sharp rap over the knuckles last week by 10 Nobel prizewinners and one former Presidential science adviser for trying to make political capital out of the fact that the United States made a clean sweep of this year's Nobel prizes. Presenting the National Medal of Science to 15 American scientists last month, he took the opportunity to score a few political points, and without mentioning Jimmy Carter by name said that the Nobel sweep would "surely put to rest" suggestions that the United States had lost respect around the world. He then argued that there is a need to "bolster research and development to achieve national goals".

The remarks, and their implication that the Administration should share the credit for the Nobel awards, were attacked in a statement drafted by George Kistiakowsky, professor of Chemistry at Harvard and former science adviser to President Eisenhower, and signed by 10 Nobel prize-

winners including the winner of this year's award for Chemistry, William Lipscomb. The statement noted that "Nobel Prizes usually reflect work done over long periods of time. This year's prizes do not, therefore, reflect this year's strengths". The statement went on to argue that Mr Ford's budgets "have not been such as to encourage the growth of American science. The current appropriation for the National Science Foundation is actually 10% lower than it was in the year when Mr Ford took office." Other signatories were Kenneth Arrow, Julius Axelrod, David Baltimore, Owen Chamberlain, Carl Cori, Donald Glaser, Salvador Luria, E. M. Purcell and George Wald.

ESF optimism

At the conclusion of the European Science Foundation's second annual general assembly in Strasbourg last week the president of its Executive Council, Sir Brian Flowers, said he detected the emergence of a single European voice in science. The

assembly had accepted the findings of ad hoc committees on genetic manipulation and astronomy.

One material consequence is that a European committee will be established under the aegis of the ESF both to discuss recombinant DNA research and to keep under continuous review the guidelines covering it. The committee will consist of representatives of the various national advisory bodies concerned together with representatives from both the EMBO Standing Advisory Committee and the European Medical Research Councils.

Acceptance of the astronomy committee's recommendations means that Europe's instrumental resources will soon be concentrated on a mountain ridge of La Palma in the Canary Islands. The first major step would involve moving the British Isaac Newton Telescope; Sweden's instruments now at Anacapri in Italy would follow, and a new Austrian telescope would come later. The Observatory itself would be Spanish.

At 10.30 a couple of Sundays ago I cut a tape across a footpath and led a crowd of 361 men, women and children on a sponsored walk around Grafham Water, one of the largest man-made lakes in southern England. Our purpose was to raise money for the Ouse Valley Wildlife Appeal to enable the Bedfordshire and Huntingdonshire Naturalists Trust, a voluntary conservation organisation of which I am president, to buy land for nature reserves. Almost all the walkers completed the modest circuit of ten miles, and so called upon the maximum generosity from those who had agreed to support the appeal, at rates ranging from a halfpenny to a pound a mile. My own efforts produced £56.20; the whole exercise raised more than £2,000. The Trust's last acquisition was Upwood Meadows, 14 acres of botanically interesting meadow probably unploughed since the Black Death; it cost us £5,000, so the walk paid off the debt on about five acres.

England is one of the most crowded areas in the world. The growing population, industry, affluence and increasing mobility are putting intense pressure on wild plants and animals and on the habitats which support them. Modern agriculture is changing the look of the countryside, and the wholesale removal of hedges, rows and copses means that many birds, butterflies and flowers which were formerly common and widespread are difficult for the non-expert to find. Sites for scientific study, for

education and for ecological research are disappearing.

Fortunately there are in Britain official bodies like the Nature Conservancy Council and the Countryside

Walks for wildlife**KENNETH MELLANBY**

Commission which are charged with conserving wildlife and rural amenity, and this they do admirably to the limit of their meagre resources. It is encouraging that the Nature Conservancy Council has been able to designate an increasing number of outstanding National Nature Reserves in recent years, by purchase, lease or "nature reserve agreement". This last system is one by which liberally-minded landlords agree to restrict their activities so that the area will

retain its scientific importance. It is feared, however, that new legislation may compel some such landlords or their heirs to sell their property, and that the buyers may be less willing to give priority to a few rare orchids or to wildfowl.

It is therefore fortunate that official efforts are so often supplemented, and sometimes surpassed, by the many voluntary conservationist organisations in Britain. Critics may complain that conservationists are mainly a middle class elitist group, and this is to some extent true—and why not—but they are making great efforts to bring all sections of the population into their ranks.

Many of the reserves established by County Naturalists Trusts are conveniently situated to be used as open-air classrooms by local schools. When the pupils become involved in strenuous management exercises, such as removing unwanted scrub which is crowding out the more exciting plants, they may become converts to conservation. Even sponsored walks involve a new section of the population, and if, as at Grafham, these go through reserves with simple nature trails marking clearly some of the points of importance, the walkers' temporary interest may be made permanent. It is estimated that nearly five thousand of those who sponsored the walkers were not otherwise concerned with conservation: perhaps the success of the venture will turn their sympathy to real interest and support.

news and views

DNA sequences coding for more than one protein

from Benjamin Lewin

THE single strand DNA phages of *Escherichia coli* are amongst the smallest viruses known (only the RNA phages are appreciably smaller) and are therefore of special interest for the strategies evolved by their genomes to allow successful reproduction with such limited genetic information. In fact, a paradox in the organisation of their genomes has recently been suggested by the identification of a greater number of phage-coded protein products than it appears can be accommodated within the complexity of the genome. Both types of single strand DNA coliphage possess a circular genome, in the case of the icosahedral phages ϕ X174 and S13 fairly well characterised as about 5,500 bases, and for the filamentous phages f1, fd, M13, apparently somewhat larger.

A genome of 5,500 bases should have a maximum coding capacity equivalent to some 200,000 daltons of protein. But measurement of the proteins induced by infection with ϕ X174 identifies a total of nine species, with a combined weight approaching 250,000 (Benbow *et al.*, *J. Virol.*, **10**, 99; 1972; Godson, *J. molec. Biol.*, **57**, 541; 1971). Each of these protein products can be equated with one of the nine identified genes of the phage. In spite of some uncertainties about the sizes of two of the proteins, it is clear that their total mass is appreciably greater than is to be expected of the phage genome.

One mechanism utilised by the phage is to produce two proteins from one gene. Products of gene *A* can be identified with weights of about 60,000 and 35,000 daltons, and Linney and Hayashi (*Nature new Biol.*, **245**, 6; 1973) showed that the smaller protein represents the C-terminal part of the larger. Probably it results from an internal initiation of translation about halfway along the gene. The functional relationship between the two products is not clear.

A situation more difficult to resolve has been presented by the genes *D*, *E* and *J*, whose products have been identified as a protein of about 15,000 daltons needed for particle assembly, a protein of about 17,500 daltons needed for lysis,

and a particle component of about 9,000 daltons. The construction of a restriction fragment map for ϕ X174 suggested that there could not be room for all three genes in the part of the genome where their mutations lie. Restriction maps of ϕ X174 DNA have been developed with several different enzymes, including *Hind*II, *Hae*III and *Hpa*II; calibrating the sizes of the fragments with known standards generated a total length for the genome of 5,200–5,400 bases, slightly less than the previous estimates of 5,500 (Lee and Sinsheimer, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 2882; 1974). By using a marker rescue technique, Weisbeek *et al.* (*Virology*, **72**, 61; 1976) recently were able to locate mutations on to *Alu*I, *Hind*II or *Hae*III fragments, and thus to calibrate the restriction map with the genetic map. This allowed the maximum possible size of each gene to be calculated, and in most instances this suggested that the protein products must be slightly smaller than the sizes previously estimated. But in the region where genes *D*, *E* and *J* lie, the sizes of the restriction fragments exclude the possibility that there might be three contiguous genes coding for proteins totalling more than 40,000 daltons. This seemed explicable only in terms of the postulate that mutants thought to identify *J* might in fact reside in *E*, eliminating the *J* gene from the map, but at the same time raising a question about the origin of the *J* protein and its relationship to the *E* protein.

In a striking demonstration of compact genetic organisation, Barrell, Air and Hutchison (page 34 of this issue of *Nature*) now resolve this problem. Using the "plus and minus" technique for DNA sequencing developed by Sanger and Coulson (*J. molec. Biol.*, **94**, 441; 1975), they have determined the sequence of genes *D*, *E* and *J*. (In fact, the entire sequence of ϕ X174 DNA has also been determined and is quoted as not more than 5,400 nucleotides, confirming the limits on genetic complexity previously established, and in good agreement with the total lengths of the restriction fragment

maps.) The sequence of the *D* gene was unequivocally correlated with its product by determining the sequence of the protein. The termination codon of gene *D* overlaps the initiation codon for gene *J* by one nucleotide: thus in the sequence TAATG, the first three bases provide the ochre codon terminating gene *D* while the last three bases provide the initiator for gene *J*. The following sequence can be defined as gene *J* by virtue of its equivalence with the amino acid sequence of a small protein isolated from the virion, which presumably corresponds to the product previously identified with *J*. However, the *am6* mutation that had been taken to define *J* genetically lies 179 nucleotides before the initiation codon for *J*, substantiating the suggestion of Weisbeek *et al.* (*op. cit.*) that it lies in another gene.

Where does gene *E* lie? Marker rescue experiments identified the location of two mutations, the classical mutation *am3* that has been taken to identify gene *E*, and the mutation *am6* that Weisbeek *et al.* suggested lies in *E* rather than *J*: both lie within the sequence equated within gene *D*. By determining the sequence surrounding the mutant amber codon, it is possible to define the phase in which gene *E* is read. This proved to be displaced one base to the right (that is in the direction of reading) from that of gene *D*. By scrutinising the sequence of gene *D* for an initiation codon (in association with a ribosome binding sequence) and a termination codon in this reading frame, it is possible to deduce that gene *E* resides within the latter part of gene *D*, and is read in a different phase (corresponding to a protein of 10,000 daltons, less than some previous estimates). Thus this sequence of DNA codes for two proteins.

How this situation may have evolved can be a subject only of speculation, but Barrell *et al.* suggest that probably gene *D* arose first, and that some event then led to the translation of part of it in a different phase, it so happening that the protein product possessed a high proportion of hydrophobic amino

acids that rendered it suitable to interact with the cell membrane, leading to the evolution of a lysis function. Of course, the evolutionary constraints upon the sequence representing both proteins must be very severe and it remains difficult to estimate how much scope there might be for variation in the sequences of the two overlapping functions. And, of course, overlapping expression must mean that all mutants in gene *E* also carry alterations in gene *D* (and *vice versa* within the region of overlap): while some of these mutations may affect one protein but not the other (due to third base degeneracy) it will be interesting in evolutionary terms to determine the general relationship between effects on *D* and *E* function. A possible utilisation of the overlap by the phage as a control is that one might expect ribosomes translating *D* to interfere with access to the initiation codon of *E*; this predicts that mutants causing termination early in *D* might have increased expression of *E*.

The complete sequence of the phage DNA will no doubt reveal whether the strategem of overlapping expression is used elsewhere in it, but the possibility is at least raised by the observation that the products of genes *A*, *B* and *C* have an estimated total molecular weight apparently somewhat greater than could be coded by this region of the genome.

What is the organisation of the genome of the filamentous phages? The genetic map constructed by Lyons and Zinder (*Virology*, **49**, 45; 1972) places the eight genes in a circular array; and with one reversal of order this was confirmed by the restriction maps calibrated with mutant locations in several laboratories (Van den Hondel *et al.*, *Eur. J. Biochem.*, **53**, 559; 1975; Seeburg and Schaller, *J. molec. Biol.*, **92**, 261; 1975; Horiuchi, Vovis and Zinder, *J. molec. Biol.*, **95**, 147; 1975). Proteins have been identified for six of the genes in two series of experiments; the results are in good agreement and suggest a total for the phage protein products of about 206,000 daltons (Model and Zinder, *J. molec. Biol.*, **83**, 231; 1974; Konings, Hulsebos and Van den Hondel, *J. Virol.*, **15**, 570; 1975). In addition, Model and Zinder identified a protein of 12,000 daltons, apparently phage coded but not yet equated with any gene.

Varying estimates have been taken for the size of the filamentous phage genome. Taking an estimate of 6,400 bases, and assuming that the genes *VI* and *VII* whose products are unidentified are about 250 bases each, led Van den Hondel *et al.* (*op. cit.*) to infer the presence of an unaccounted region of some 300 bases, which they located between genes *II* and *V* and suggested

might code for the protein of 12,000 daltons. Taking an estimate of 6,800 bases, and assuming that genes *VI* and *VII* are small, led Vovis, Horiuchi and Zinder (*J. Virol.*, **16**, 674; 1975) to suggest that there must be a considerable amount of intercistronic material, which they placed between genes *IV* and *II*. The assumption that genes *VI* and *VII* are small is supported by the mapping of known mutations to restriction fragments, but as is clear from the location of unaccounted regions in different sites, there is some latitude in the construction of the map, resulting principally from the uncertainty as to where the ends of genes lie. (The restriction fragments of these phage genomes have not been sized with respect to outside standards but only relative to each other, which makes the construction of a physical map dependent upon the size assumed for the total genome.)

It has generally been assumed that the size of the filamentous phage genome is close to 15% greater than

that of ϕ X. This would suggest a length of not more than 6,200 bases, which is only 600 bases greater than the 5,600 bases required to code for the six proteins of identified origin. If there were no intercistronic region, this would leave genes *VI* and *VII* able between them to code for some 22,000 daltons of protein. If an unidentified gene codes for the 12,000 dalton protein, then only 300 bases (or 11,000 daltons of coding capacity) remains for both these genes. In contrast to these calculations, Berkowitz and Day (*J. molec. Biol.*, **102**, 531; 1976) used biophysical means to measure a length for fd DNA of 5,740 (± 210) nucleotides. This would at best place a severe restriction on the length of DNA available to represent genes *VI* and *VII*; and if these genes should prove to code for larger protein products, or if the 12,000 dalton protein proves to represent a new gene, there would be the same paradox as seen with ϕ X174, with insufficient DNA to code for the phage products. \square

Lymphoid cell interactions in Japan

from Marc Feldmann

A Symposium entitled Cell Interactions in the Initiation and Regulation of the Immune Response, organised by Drs Yamamura and Hamashima, and sponsored by the International Union of Immunological Societies, was held in Kyoto, on September 1-4, 1976.

CELL interactions in the immune response were first recognised in 1966, with the work of Claman and his colleagues¹, and rapidly confirmed and extended by Miller², Davies³, Mitchison⁴, and others. At that time only interaction (or collaboration) between thymus derived (T) and bone marrow derived (B) lymphocytes was known, but the evidence of the following 10 years has shown that every immunological phenomenon involves interactions between several distinct cell types and their products. This symposium covered the whole spectrum of

modern cellular immunology and only a few of the aspects discussed can be reported here. Since lymphocyte heterogeneity is at the root of all these interactions recent developments in this field will take priority.

The many different surface antigens of lymphocytes have been exploited to purify different lymphocyte populations^{5,6}. The Thy-1 antigen which distinguished T from B cells⁶ is the most used. The three best characterised Ly (lymphocyte) alloantigens, Ly-1, Ly-2, and Ly-3, have been used by Cantor, Boyse and colleagues to define three subsets of T cells, bearing Ly-1,2,3, Ly-1, or Ly-2,3 antigens, which are present in decreasing proportions in the peripheral lymphoid pool.

H. Cantor (Harvard University) summarised recent work showing that helper T cells and cells involved in the mixed lymphocyte reaction (Ly-1) are distinct from cytotoxic T cells (Ly-2,3)⁷. The fact that suppressor T cells are also in the Ly-2,3 subset⁸, which is the smallest (5-10% of peripheral T cells) raised the interesting possibility that suppressor cells and cytotoxic cells may be identical, and the specificity of allo-aggressive suppressor cells like killer cells for the H-2K or D regions, rather than the I region was cited to support this view⁹. However, recent studies by Beverley *et al.*¹⁰ indicate that antigen specific suppressor cells (reactive to proteins) may be separated from cyto-

Correction

E. G. RICHARDS in an article in *News and Views* (*Nature*, **263**, 369; 1976) on September 30 entitled 'Complementary mispairs' inadvertently misnamed transitions and transversions on page 369. The word "transversions" on line 21 should be replaced by "transitions" and *vice versa* on line 24.

toxic T cells (reactive to H-2 antigens) by the use of anti-Ia antiserum, which lyses the former, and also by anti-Ly-1.1, which lyses cytotoxic cells of the CBA strain. On the other hand, the precursors of suppressor cells are usually not lysed by anti-Ia antiserum¹¹, and thus the two cell types could still be closely related.

It is now clear, however, that the Ly-1 and Ly-2 populations belong to different lines of differentiation and are not sequential stages in a single lineage¹⁴. Cantor and his colleagues have shown that mice depleted of T cells (thymectomised, irradiated and bone-marrow-reconstituted mice or "B mice") and repopulated with Ly-1 T cells only were not able to perform any of the functions of Ly-2,3 cells, even many months later; and conversely "B mice" repopulated with Ly-2,3 cells could express cytotoxicity and suppression, but not other T cell functions.

There is great interest in the role of the major histocompatibility complex (MHC) in immune responses. One aspect which has attracted attention is the prohibition of cell interactions across allogeneic barriers where MHC differences are involved. This has been reported for T-B interactions by Katz and colleagues¹⁵, for T-macrophage interactions by Rosenthal and Shevach¹⁴ and Erb and Feldmann¹⁶, and for T cell killing, by Zinkernagel, Blanden and Doherty¹⁷. Several explanations have been suggested for these restrictions. One is that a molecule controlled by the MHC must be "shared" or recognised for successful interactions to occur¹⁵. An alternative suggestion is that mixing histoincompatible cells may induce active suppression^{18,17}. D. H. Katz (Harvard University), for example, found that suppressor cells are induced when F₁ thymocytes are primed in an irradiated parental mouse. These suppressor cells may explain the genetic restrictions on T-B collaboration found in earlier experiments¹⁵. Support for this possibility was discussed by H. Cantor and R. K. Gershon (Yale University) who have shown that removal of Ly-2,3 cell populations (which contain suppressor cells) permits the residual T cells to collaborate with histoincompatible B cells in the primary response *in vitro* to sheep red cells. Independently, Dutton and his colleagues¹⁷ have obtained similar results using anti-Ly antisera and cell separation techniques, indicating that allogeneic effects can suppress interactions between histoincompatible T and B cells. Thus, there is no doubt that suppression explains some examples of the failure of histoincompatible T and B cells to interact. Whether all such failures can be attributed to suppression is not yet clear.

EGF and viral transformation

from Robin A. Weiss

EPIDERMAL growth factor (EGF) was discovered by Stanley Cohen (*J. biol. Chem.*, **237**, 1555; 1962) when he was purifying nerve growth factor from the submaxillary salivary gland of male mice. Cohen noted that the factor stimulated the proliferation and differentiation of the epidermis, as reflected by precocious opening of the eyelids and eruption of the incisors in baby mice. Since that time it has been Cohen's remarkable achievement to purify and sequence murine EGF (Cohen and Savage, *Recent Progress in Hormone Research*, **30**, 551; 1974). It is a single-chain polypeptide containing 53 amino-acid residues with a molecular weight of 6,045. The molecule has been well conserved during evolution and human EGF extracted from urine shows only minor differences in amino-acid sequence to murine EGF. Recently it has become evident that EGF will stimulate proliferation of a variety of both epithelial and fibroblastic cells in culture. Its specific mitogenic action on non-proliferating cells in culture provides a much more convenient and quantitative assay than examining eyelid opening *in vivo*.

Last year Cohen's group showed that cells in culture which respond to the mitogenic action of EGF possess specific receptors for EGF on the cell surface (Carpenter, Lembach, Morrison and Cohen, *J. biol. Chem.*, **250**, 4297; 1975). EGF receptors were assayed by measuring the binding of ¹²⁵I-labelled EGF to the cell surface. Cells of many species bound EGF, but certain types, including a human lymphoblastoid line (NC-37) and rat cells transformed by mouse sarcoma virus

(KNRK) and by Rous sarcoma virus (XC) apparently lacked EGF receptors. Reduction in the binding of other hormones to transformed cells has also been reported, for example, in a recent study of insulin receptors on BALB/3T3 cells by Thomopoulos, Roth, Lovelace and Pastan (*Cell*, **8**, 417; 1976). The binding of insulin varied with the level of proliferation in cell population and the reduction seen in transformed clones was not specific to the transforming agent. However, the presence of EGF receptors appears to be more specific. In this issue of *Nature* (page 26), Cohen, in collaboration with Todaro and De Larco, reports additional data on the binding of EGF to the same cell types transformed by different tumour viruses. For example, the A31 clone of mouse BALB/3T3 cells was transformed by SV40, two strains of mouse sarcoma virus (MSV) and Rous sarcoma virus (RSV). Only the MSV-transformed subclones failed to bind EGF. This remarkable specificity of binding was true for transformed subclones of other types of cell such as Swiss 3T3, NRK and Mink lung. In each case, only the subclones transformed by MSV or by feline sarcoma virus failed to bind EGF.

Solely on the basis of the specific failure to bind EGF, the authors postulate that MSV might transform cells by coding for an EGF-like molecule in part of its sarcoma-specific genetic sequences. This EGF analogue would then block the receptors and stimulate the cells to grow. This will hardly provide the whole explanation of viral oncogenesis, but it can be tested.

It now seems clear from the reports of several workers that suppression is mediated by products of the I region. T cell suppression in mice, for example, is mediated by an antigen-specific T cell factor with a molecular weight of about 50,000 and which does not operate across H-2 barriers^{18,19} (T. Tada, Chiba University). This factor is absorbed by antisera reactive to products of the I-J subregion, which also seems to code for the receptor for the suppressive factor. The cells carrying the receptors (sometimes known in this context as acceptors) were found not to be helper T cells, but nylon-wool-adherent T cells which could be killed by anti-I-J serum and complement^{18,19}. Allotype specific suppressor T cells can also be killed by antiserum containing antibody to I-J region products²⁰⁻²² (L. Herzenberg

and D. B. Murphy, Stanford University).

Two generalisations seem to be possible on the basis of this and other work. First, that the I region is functionally specialised, the I-J subregion being involved in suppression and the I-A subregion in macrophage or T-cell helper functions. Second, the products of the I region act on target cells through receptors controlled by the same I subregion^{23,24}.

M. Taniguchi (Chiba University) discussed studies performed with Tada on a factor obtained from lysed antigen-primed spleen or thymus cells which augmented IgG antibody responses, provided that factor donor and recipient (in culture) were identical in the I-A region. This factor seems to be different from the helper factor described by

Taussig and Munro²² which does not require I-A identity. Furthermore, the material isolated by Taniguchi and Tada unlike that of Munro and Taussig does not induce immune responses in the absence of other T cells, suggesting that it is an amplifier factor, rather than a helper factor which replaces T cell function. Thus, there are now four examples of I region factors each of which acts through a receptor on another cell type, but which is controlled by the same I subregion¹⁸⁻²⁴. The presence of (at least) three pairs of genes for factors which augment responses and their receptor each detected by different techniques in different assay systems, but all controlled by I-A, leads to the obvious question as to whether the factors described by Taussig²³, Erb²⁴, and Taniguchi¹⁸, are really distinct members of a 'family' of factors, or whether they are the same, but seem different because of the assays used. T cell suppression is also under control of non-H-2 genes. This was reported by Tada on the basis of the inability of cells from the A/J mouse strain to make suppressor factor, and of cells of the B10 congenic strains to accept suppressor factor^{18,19}.

The mechanism of suppression of the immune response by T cells is not yet known in detail. Tada noted that suppression involves an intermediate cell, which is involved in suppressing helper cells. J. F. A. P. Miller (Walter and Eliza Hall Institute, Melbourne) reported that suppressor cells induced during tolerance induction cannot suppress on their own but require the participation of adherent cells²⁵. E. Diener (University of Alberta, Edmonton) also described studies in which adherent cells were involved in the mediation of tolerance²⁷. This suggests that adherent cells (perhaps T cells, or cells of the macrophage/monocyte series) are involved in the effector phase of suppression. Clearly the relationship of this cell, which may be of hitherto unknown type, to known cell types, is an important question for classification.

Miller's work emphasised that we do not yet know how many types of lymphocyte there are. He reported that cells which suppress induction of the delayed hypersensitivity response in mice are Ly-1 cells, unlike the Ly-2,3 suppressor cells which inhibit antibody response. This difference could be explained if there is T-T interaction in induction of the suppressor cells of the delayed hypersensitivity response with Ly-1 cells stimulating (*in vivo*) Ly-2,3 precursors of suppressor cells to become active suppressor cells. Such a T-T interaction in the induction of suppressor cells has been reported previously²⁸. T. Hamaoka (Osaka Uni-

versity, Japan) reported studies which confirmed the T-T interaction concept, using hapten reactive T cells.

The field of cell interactions in the immune response has clearly expanded considerably over the past 10 years, and it is predictable that the next 10 years will see a deepening awareness of the complexity and richness of the cell interactions and suppressive effects which regulate and integrate immune response.

Gravity experiments

from Malcolm MacCallum

STANDARD introductory courses in general relativity give an account of the "three crucial tests" discussed by Einstein in his famous 1916 paper: the gravitational redshift, the bending of light-rays and the advance of perihelia of planets, especially Mercury. These established the superiority of Einstein's theory to the others of the day, but many more theories have been invented in the intervening 60 yr. Only since 1970 have new experimental tests become available.

The classic tests are of course still actively pursued. The Eötvös experiment, which checks that the gravitational acceleration of laboratory bodies is independent of their composition, was improved to one part in 10^{13} by

V. A. Braginsky and V. I. Panov in 1971. Gravitational redshift measurements, both astronomical and terrestrial, which can be interpreted as a test of the universality of free-fall (given energy conservation), are accurate to a few per cent. Clocks in spacecraft should improve on this, and a satellite experiment is already in progress.

It is difficult to carry out the second "crucial test" with visible light. The Texas team which recently reported on observations made in Mauretania in 1973 (*Astr. J.*, **81**, 452; 1976) quote an error of about 12%. Measurements of the deflection of radio waves are more accurate. The most recent result, announced by E. B. Fomalont and R. A. Sramek (*Phys. Rev. Lett.*, **36**, 1475; 1976) quotes an error of about 1%. This limit cannot really be improved without detailed knowledge of the conditions in the solar wind plasma through which the waves pass.

The perihelion measurements have been checked by radar to about 1%. Their meaning was thrown into question 9 yr ago when R. H. Dicke and H. M. Goldenberg observed an apparent oblateness of the Sun which suggested a solar quadrupole moment large enough to produce a significant part of the effect, but H. A. Hill and R. T. Stebbins (*Astrophys. J.*, **200**, 271; 1975) found a much smaller corrected value. All three of the "crucial tests" are thus in good agreement with Einstein's theory.

It has been known for some time that further effects are potentially observable. The first of these actually to be measured was the "fourth test of general relativity", the time-delay of electromagnetic waves passing near the Sun. This has been measured by radar echoes from Mercury and Venus and more recently, by J. D. Anderson *et al.* (*Astrophys. J.*, **200**, 221; 1975), using the Mariner 6 and 7 spacecraft, to about 3%.

Possible experiments on gravity have been extensively examined since 1968 by K. D. Nordtvedt at Montana State University and by a group at California Institute of Technology led by K. S. Thorne. The simplest theories to analyse are those in which the influence of gravity on matter is completely described by a (Riemannian) metric, as it is in general relativity. These theories differ in how the matter generates the metric. The analysis proceeds by computing all possible effects arising from the lowest order corrections to Newtonian theory. The most general form of this "parametrised post-Newtonian framework", due to C. M. Will (*Astrophys. J.*, **185**, 31, 1973) involves 10 parameters dependent on the particular theory considered. Theories which do not fit within this framework are more difficult to analyse systematically, but several of them have already been

shown to be in conflict with observation. The programme has drawn attention to the possibility of new types of experiment and new experimental results on two of these have been announced recently.

One of them is the Nordtvedt effect, which arises if gravitational energy does not obey the equivalence of inertial and passive gravitational mass. Since the gravitational energy content of laboratory bodies is extremely small, this is not tested by the Eötvös experiments. Laser-ranging of the Moon has been carried out since 1969 to search for the effect. The results obtained and analysed by a team of seventeen from nine American institutions (J. G. Williams *et al.*, *Phys. Rev. Lett.*, **36**, 551; 1976) and independently analysed by I. I. Shapiro, C. C. Counselman III and R. W. King (*Phys. Rev. Lett.*, **36**, 555; 1976) show that the equivalence principle for gravitational energy is true to about 3% accuracy.

The other new result concerns variations in gravimeter readings, like those produced by Newtonian tides of the solid Earth. As shown by C. M. Will, these variations could contain post-Newtonian contributions dependent on lunar, solar and sidereal periods with 12-h, 24-h and annual oscillation. Most of them are too small to be detectable. Nevertheless, existing data enabled Will to place strong limits on the influence of any preferred reference frame (essentially an absolute rest frame), and to show, for example, that Whitehead's action-at-a-distance theory of gravity, which had lasted 50 yr, predicted effects 200 times larger than experiment allowed. Effects of these types have been further restricted by new data produced by R. J. Warburton and J. M. Goodkind of the University of California at San Diego (*Astrophys. J.*, **208**, 881; 1976) using a superconducting gravimeter. The main uncertainty lies in the calculation of the Newtonian effects, especially those arising from the shifting weight of the oceans.

All the experiments mentioned above, together with those also analysed by Will on the equivalence of active and passive gravitational mass and on the Earth's rotation rate, are in agreement with the predictions of general relativity. The only discrepant result is the time-dependence of the gravitational constant given by T. C. van Flandern (*Mon. Not. R. ast. Soc.*, **170**, 333, 1975) but even this differs from zero only by twice the quoted error. Further results from these measurements and from, for example, the precession of gyroscopes in satellites, can be hoped for in the next decade.

One might thus think that Einstein's theory was proved. Certainly the work

of the past 5 yr has severely damaged the credibility of those rival theories available in 1970. Unfortunately, any finite number of effects can be fitted by a sufficiently complicated theory. Indeed, all the general-relativistic predictions for the post-Newtonian effects can be replicated to arbitrary accuracy or even exactly by suitably constructed alternative theories. Aesthetic or philosophical motives will therefore continue to play a part in the widespread faith in Einstein's theory, even if all tests verify its predictions. □

Histone gene organisation

by Eleanor Lawrence

OVER the past few months a detailed picture of histone gene organisation at the level of the repeating unit has begun to emerge, based on the work of several groups who have approached the problem with a variety of different techniques.

In a recent set of papers (Gross, Probst, Schaffner and Birnstiel, *Cell*, **8**, 455; 1976; Schaffner, Gross, Telford, and Birnstiel, *Cell*, **8**, 471; 1976; Gross, Schaffner, Telford and Birnstiel, *Cell*, **8**, 479; 1976) Max Birnstiel and his colleagues have ordered the individual genes within the histone repeat unit of sea urchin DNA—in this case *Psammechinus miliaris*. They have ordered the genes by hybridising restriction endonuclease-generated fragments of enriched *Psammechinus* histone DNA with highly-purified individual labelled histone mRNAs isolated from the labelled 9S polyribosomal RNA from a closely related sea urchin *Paracentrotus lividus*, each of which has been assigned to one of the five histones H1, H2A, H2B, H3 and H4, by comparison of the *in vitro* translation products with *Paracentrotus* histones labelled *in vivo*.

A major difficulty in previous attempts to order the individual coding sequences in this way, has been the separation and identification of mRNAs coding for histones H2A, H2B and H3. By a careful choice of conditions, based on a study of the complex behaviour of *Paracentrotus* histone mRNA on electrophoresis under various denaturing conditions, Gross *et al.* were able to obtain five distinct mRNAs of sufficient purity that on translation in a wheat germ cell-free system four of the mRNAs could be characterised as coding mainly for a single protein which could then be identified as one of the histones by comparison with ³H-leucine and ³H-lysine labelled histones produced *in vivo*.

From digestion of enriched histone

DNA by a set of four restriction enzymes a detailed restriction map of the complete unit was constructed. Using combinations of restriction enzymes the 6 kb complete repeat unit was subdivided into five fragments. Each fragment hybridised with only one of the purified mRNA fractions and so by collating the restriction map and the hybridisation data, the individual coding sequences could be ordered within the repeat unit as shown below.

The polarity of the *Psammechinus* histone genes has also been determined. Limited resection by lambda exonuclease (which digests from the 5' end only) of the complete repeat units obtained after restriction with *HindIII* or *EcoRI*, and subsequent hybridisation to H4 mRNA showed that the polarity of the H4 gene was 5' H2B→H4→H1 3'.

Further experiments of this and other groups have shown that the histone coding sequences all lie on the same DNA strand, and so it follows that all the coding sequences have the same polarity, and transcription will proceed in the direction H4→H2B→H3→H2A→H1.

Groups at Stanford and CalTech have since reported a similar order for the histone genes in another sea urchin—*Strongylocentrotus purpuratus* (Cohn, Lowry and Kedes, *Cell*, **9**, 147; 1976). In this case pure histone DNA was isolated by cloning the two *EcoRI* restriction fragments of ~2.2 and ~4.8 kb, which make up the complete '7 kb' histone repeat unit in plasmids pSp17 and pSp2, respectively. Further dissection with restriction endonucleases enabled a detailed restriction map of the repeat unit to be constructed and fragments corresponding to various classes of histone mRNA were identified by hybridisation. An earlier tentative assignment of these mRNAs to individual histones (see *News and Views*, **259**, 361; 1976) has required revision, and the order of the genes has now been determined by direct sequencing of portions of the plasmid-cloned DNA fragments corresponding to the different mRNA classes (Sures, Maxam, Cohn, and Kedes, unpublished) and matching them with the known histone amino acid sequences. The genes appear to be ordered in exactly the same sequence as those in *Psammechinus*.

A detailed quantitative assessment of the relative positions of the coding and spacer regions is provided in the

accompanying paper by Wu *et al.* (Wu, Holmes, Davidson, Cohn and Kedes, *Cell*, **9**, 163; 1976), who have hybridised total histone mRNA to single-stranded DNA from the histone plasmids pSp2 and pSp17.

Since the mRNAs hybridise only to the complementary coding sequences, the arrangement of coding and non-coding regions can be seen directly in the electron microscope after a novel treatment with T4 gene 32 protein which preferentially stains the single-stranded regions of the histone plasmid DNA-histone mRNA hybrids (Wu and Davidson, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 4506; 1976). As expected, they found three RNA:DNA hybrid regions on pSp2 and two on pSp17 accounting for the five histone genes, interspersed with spacer DNA—definitive proof that each gene is only repeated once in each repeat unit. Direct measurements allow them to independently assign most of the duplex regions to specific histone genes, constructing a map which agrees with those obtained by other methods.

Portmann, Schaffner and Birnstiel

(page 31 of this issue of *Nature*) have also directly demonstrated by electron microscopy five coding regions interspersed with spacer DNA in the *Psammechinus* repeat unit DNA cloned in phage lambda, by making use of the fact that the AT-rich DNA of the spacer regions denatures at a lower temperature than the GC-rich coding sequences forming open loops along the DNA. The GC-rich regions correspond well in size to the individual histone protein sequences.

Detailed sequencing of the repeat unit at the nucleotide level is now underway, made possible by the ability to obtain pure DNA fragments by cloning in phage or plasmids. Before too long, nucleotide sequencing may well have identified any regions of homology between the non-transcribed DNA in these and other genes, or between the histone spacer sequences themselves. Preliminary evidence (Cohn *et al.*, *Cell*, *op. cit.*), indicates that most of the histone spacer sequences are unlikely to be shared with other genes, and that there is also little homology between the individual spacer sequences. □

keeping population levels steady

Hogarth concludes with speculation on the causes of extinction of dragons, despite persistent accounts of dragons and similar animals even in the present century, the typical mediaeval dragon was certainly extinct by the late 18th century. One contributing factor was commercial over-exploitation, primarily for pharmacological purposes. Only once was conservation legislation passed to protect dragons. This was in Rhodes, in 1345, when the king forbade any knight to attempt to slay a local dragon (although Hogarth conjectures that this edict stemmed from concern for the knights, not the dragon). If we accept the notion that dragons were extreme K-selected animals, then their rapid extinction under the diverse pressures exerted by man is not surprising (see for example, *Nature*, **257**, 737–738; 1975).

Hogarth's article is undoubtedly seminal, but I find it in some respects excessively uncritical. In discussing the evolution of dragons, and other "related species such as the cockatrice and griffon", Hogarth suggests they "probably originated as a distinct group only 5,000 years ago". Quite apart from the inherent implausibility of this statement, it is well to begin by getting clear the morphological details of the animals loosely grouped together here. These can be obtained from bestiaries, or from any heraldry text. Setting aside relatively minor differences, such as whether the feet have talons or claws, or whether the head has teeth or a beak, the basic difference is that the griffon and the canonical dragon are six-limbed (four legs, two wings), whereas the wyvern and cockatrice are four-limbed (two legs, two wings).

This is an absolutely fundamental distinction. One of the most conservative features of vertebrate evolution is the tetrapod morphology: this may be seen in any museum exhibit of the

The ecology of dragons

from Robert M. May

ALTHOUGH much studied in earlier times, dragons and their ilk have been largely neglected in the recent upsurge of interest in animal ecology and behaviour. An article by Hogarth (*Bull. Brit. ecol. Soc.*, **7**[2], 2–5; 1976) seeks to remedy this neglect.

In view of the lack of contemporary observational evidence, Hogarth necessarily relies on a survey of earlier sources. Most of these are from the 17th and early 18th century, an age when scientific curiosity was flowering. Later publications are increasingly sceptical, although Hogarth notes published doubts on the existence of dragons as early as Caxton's (1481) *Mirror of the World*.

Dragons appear to have been both omnivorous and voracious. Different records testify to their diet having been highly variable in both composition and quality: one dragon ate two sheep every day, and another which was kept captive by Pope St Sylvester consumed 6,000 people daily. The population density was also highly variable (presumably in a way which correlated with the per capita food requirements): "in England, indigenous dragons were solitary and it is doubtful whether the resident population averaged more than a few dozen, although occasional migrant flocks of up to 400 were seen: in India, by contrast, the marshes and mountains were described as being 'full' of dragons". Estimates of their life table parameters are scrappy, but

there seems to be general agreement on a typical lifespan of the order of 10^2 – 10^4 years.

The sexual display behaviour of dragons includes at least one remarkable and unparalleled manifestation, recorded by an 18th century author "Dragons, being incited to lust through the Heat of the Season, did frequently, as they flew through the Air, Spermatise in the Wells and Fountains". This may be conjectured to have had adaptive value in reducing intrinsic fecundity. Such long-lived beasts would seem to have been at the extreme K-selected end of the r-K continuum, and would therefore be likely to exhibit behaviour which had the effect of

Mary Evans Picture Library

500,000,000 years of evolution from lobe-finned fishes through amphibians and reptiles to birds and mammals. This underlying conservatism in skeletal structure, despite great variation in outward form and function, probably reflects the relative ease of modification of genes which govern timing in development, as opposed to those governing basic structure (see for example, King and Wilson, *Science*, **188**, 107-116; 1975). The wyvern and cockatrice have this basic vertebrate tetrapod morphology, but the six-limbed dragon and griffon do not. The probable ancestry of these latter two, as an entirely separate group, therefore dates back at least to the Devonian. This basic distinction applies to other now-extinct beasts despite superficial similarities, unicorns belong with the familiar tetrapods, but the pegasus belongs with the six-limbed dragon-griffon vertebrate phylum, as do centaurs. Some angels (the humanoid-plus-wings kind) also belong in this phylum, but in view of the bewildering complications of angel morphology (once one includes cherubim, seraphim, and so on; see Davidson, *Dictionary of Angels: Including the Fallen Angels*, Free Press, 1967), this point is best not pursued.

In brief, wyvern and cockatrice can be envisaged as radiations from the basic vertebrate theme. But dragons, griffons, centaurs and angels belong to an entirely different lineage, the evolutionary history of which is shrouded in mystery.

The loose association of these two fundamentally different groups provides a striking example of the pre-Darwinian tendency to regard each species as a separate act of creation, rather than to trace logical phylogenetic relationships.

On the other hand, grouping together dragons, wyverns and the like is understandable in the light of the similarities of their ecology, behaviour and superficial appearance. They provide a dramatic example of evolutionary convergence, in the face of phylogenetic differences at least 400,000,000 years old. Such convergence implies some very tight evolutionary constraint somewhere in the "dragon" niche, a constraint hardly hinted at in Hogarth's account of their highly generalist diet and behaviour. This constraint may lie in the tendency exhibited by most dragons of record to be obsessive custodians of hordes of gold.

I conclude with the time-worn call for further research, modified by the highly contemporary remark that (if the above speculation is correct) such research may yield the literally golden fruits that grant-giving agencies increasingly desire. □

Primate behaviour and ecology

The Sixth Congress of the International Primatological Society was held at Cambridge on August 23-27, 1976. Aspects of the conference dealing with behaviour and ecology are discussed below

from F. P. G. Aldrich-Blake and
Miranda Robertson

THE theoretical thrust of much primate work in the late sixties and early seventies was loosely socio-ecological; features of social organisation such as group size and composition were related to broad ecological categories of habitat such as 'forest' or 'savanna'. While this approach sought an evolutionary explanation of primate societies, it was insufficiently precise both in its treatment of causal mechanisms of social change and in its measurement of critical ecological variables. Recent work has placed a greater emphasis on the adaptive strategies of individuals in their dealings with society and the environment.

Notable in this respect was a paper by R. M. Seyfarth, D. L. Cheney and R. A. Hinde (University of Cambridge), which sought to provide a conceptual framework within which to interpret inter-individual behaviour. Primate societies, they pointed out, can be analysed at three different levels: interactions between individuals; the long-term relations to which interactions give rise; and the structure resulting from those relationships. While patterns of interaction between individuals are often apparently complex, they may be governed by relatively simple principles. For example, networks of social grooming among adult females of four species of primate had many features in common, despite being drawn from groups of differing size and degree of genetic relatedness. Computer simulation showed that these features could be accounted for by a preference for females of high rank as grooming partners and competition for access to these preferred females. Interactions between individuals have long-term effects on their relationships; grooming partners are more likely to form coalitions during aggressive encounters than are pairs that have had fewer friendly interactions in the past. Thus the optimum individual strategy should be to maximise the benefit derived from others by maximising the time spent interacting with animals of high rank. A similar theoretical approach can be used to explain many other aspects of social behaviour; the different behaviour of immature males and females, for instance, can be related to

strategies for maximising their fitness as adults.

In contrast, sessions on ecology produced few conceptual syntheses, despite a striking increase in the quality and quantity of research in this field. Detailed accounts of primate communities in Asia, Africa and the Americas were presented, the most notable being that of T. T. Struhsaker (New York Zoological Society) and his associates in the Kibale Forest, Uganda. In all areas, leaf eaters attained higher biomasses than fruit eaters, and these higher than insectivores, but otherwise few general principles emerged. Indeed discussion revealed dissent on aims and methods, let alone conclusions.

We still do not know what factors limit the population of any primate. Availability of food is clearly a plausible candidate; K. Milton's (New York) studies of the howler monkeys of Barro Colorado Island and their habitat suggest that fruit and young leaves of suitable quality may be in short supply at some seasons. Food intake may be limited as much by the need to avoid toxins as to obtain nutrients. Milton showed that many potential foods were rich in phenolic compounds, and J. S. Gartlan and D. B. McKey (University of Wisconsin) likewise demonstrated the presence of toxins in most plant products in the Douala-Edea forest of Cameroon. On the other hand T. Iwamoto (Miyazaki University), in bioenergetic studies of Japanese monkeys in evergreen forest and gelada baboons in Ethiopian montane grassland, obtained figures suggesting that primates used only a tiny proportion of the potential food available. T. H. Clutton-Brock (University of Sussex), and other participants in the concluding discussion, considered that problems of measuring food availability were so intractable, at least in tropical forest, that any attempts were doomed to failure.

S. A. Altmann (University of Chicago) suggested that attention should be focused on species living in relatively simple habitats, and presented a mathematical model of optimal diet, to be tested on savanna baboons in Kenya. Foraging strategies to be adaptive, he pointed out, animals must eat enough of the various foods available to stay above the minimum for every nutrient and below the maximum for every toxin, at the least possible cost. While the model related these factors with elegance and simplicity, many participants thought it likely to founder on the practical problems of measuring cost, including as it does such diverse elements as energy expenditure, time, and risk of predation. Clearly we must wait some years yet before the value of this and competing approaches becomes clear.

One aspect of research on primate social organisation which seems to be relatively underdeveloped is that of communication, which was the subject of a review lecture by Peter Marler (Rockefeller University). It is still not known for certain whether the dozen or so sounds that make up the communicative repertoire of most monkeys and apes are ever used in the way that words are used to make sentences—one sound retaining the same meaning in different sound combinations—or whether it is always the complete pattern that conveys the message, and not the sum of its parts. It is almost certainly the entire sound combination, but the precise interpretation of primate calls in their natural context can be extremely difficult and Marler took the view that the effects of playing back natural calls should be very illuminating, perhaps especially in the laboratory in combination with single-unit recordings from the animals' cortex. (Neurophysiologists, who have had more experience with the problems of interpreting the calls of single units in their natural surroundings, might take issue with him on the latter point.)

What apes have certainly not done is to develop a language in the sense that man has, and in spite of the research resources poured into the attempt, they have not been conclusively shown to be able to use ours in a strictly linguistic way. Although D. M. Rumbaugh (Yerkes Primate Center, Atlanta) protests the contrary, David Premack (University of Pennsylvania) not only conceded that apes never have grasped human language, but is willing to predict that they never will.

They can, however, fairly readily learn to use abstract symbols to represent objects and actions, and they can use the symbols in strings. What is missing is the evidence that the strings are composed according to syntactic rules.

Tired of trying to satisfy professional linguists that ape use of symbols fulfils the criteria for linguistic competence, some researchers have declared they would be satisfied by a "Turing test". If a man cannot tell whether he is conversing with an ape or another man, then the ape is using language. P. A. M. Seuren, collaborating with G. Ettlinger and others at the Institute of Psychiatry (London University), has, as a linguist himself, suggested a more sophisticated test which hinges on an anomaly of human usage. We say, for instance, "Don't do this and don't do that" or "Don't do this or that", but never the logically equivalent "don't do this and that". That linguistic quirk, according to Seuren, is virtually universal in human languages. The question is, would it crop up spontaneously

in ape usage? The answer will not be available until Ettlinger and his colleagues have succeeded in teaching apes to use "or", which has so far not been done. □

Heavy ions at Caen

from P. E. Hodgson

The European Physical Society Conference on Nuclear Physics with Heavy Ions was held at Caen on September 6–10, 1976

HEAVY ion physics has developed rapidly over the last few years and the conference provided an opportunity to survey the areas that are already quite well understood, and also to discuss the extensive new data on new phenomena, and the theories that have been suggested to account for them. Caen was chosen for the Conference because a powerful new heavy ion accelerator GANIL is to be built there in the next few years.

Glancing collisions between heavy ions, in which one or two ions are transferred, are useful probes of nuclear structure, and the present state of this work was surveyed by O. Hansen and J. Garrett (University of Copenhagen). Detailed theories of these reactions have been developed, and very complicated theoretical calculations, involving the solution of coupled Schrodinger equations, are needed to analyse the data. K. Low (CEN, Saclay) showed how these calculations account for the details of the reaction mechanisms. Their very complexity does, however, make it difficult to use such reactions for nuclear structure studies. This work also needs the optical potentials that represent the interaction between the ions, and some of the latest methods of calculating these potentials were surveyed by D. Brink (University of Oxford).

Extremely complicated reactions take place when the heavy ions collide more nearly head-on. They can fuse together to form a highly excited compound system which then decays by particle emission (discussed by M. Lefort (Orsay)). If the collision is intermediate between glancing and head-on the two nuclei can orbit round each other and exchange a few nucleons, becoming highly excited in the process, before separating again. Measurements have been made of the energies and masses of the ions after these deep inelastic interactions, and some of the results were considered by J. Galin (Orsay) and by L. G. Moretto (Berkeley). The theories that have been developed to account for these data were summarised in a comprehensive review by W. Norenberg (University

of Heidelberg). The earlier theories using the classical concept of friction are now being replaced by microscopic transport theories and the spreading of the energy distribution is described by the Fokker–Planck equation. This new and detailed understanding of deep inelastic scattering was one of the more important developments reported to the conference.

When two heavy ions combine after a non-central collision, the compound system has a large angular momentum. This preferential excitation of high spin states is a useful means of studying nuclear structure, and the development of our knowledge in this area was surveyed by Z. Szymanski (University of Warsaw).

A special session was devoted to the many attempts that have been made in the past few months in several laboratories to detect superheavy nuclei, after the announcement that evidence has been found for their natural occurrence in the mineral monazite (see *Nature*, 261, 627; 1976). Samples of monazite have been bombarded with protons and the spectra of the gamma rays subsequently emitted have been measured. Detailed chemical analyses have been made of samples of the mineral and reactions between heavy ions that might lead to their production have been studied. Monazite has been bombarded with heavy ions, and the recoils examined to see if any of them could have come from superheavy nuclei, but none of this work provided any evidence in support of their existence. This does not yet destroy the evidence offered in the original papers, as there are still several important points that require more detailed examination, but the evidence in favour of superheavy nuclei now looks decidedly weaker than it did a month ago. Work will certainly continue in this exciting field. □

A hundred years ago

REFERRING TO OUR recent correspondence on "Antedated Books," a correspondent calls attention to another evil practice that has of late years crept into the publishing trade, namely, that of publishing books without any date at all. Such books are generally of small literary or scientific value, but circulate among a class who are generally unable to test their value. Of course the purpose of issuing undated books is evident; works half a century old may be palmed off on the unknowing as the genuine product of the current year.

From *Nature*, 15, November 2, 1876.

review article

Development of early stock rearing in the Near East

S. Bökönyi*

The neolithic "revolution", from hunting and gathering in human communities to animal husbandry and agriculture, seems to have originated in the Near East. A primitive kind of domestication arising from the adoption of the young of wild beasts killed by hunters seems to have preceded the deliberate breeding of domesticated strains.

STUDIES on the domestication, origin and development of domestic animals have advanced particularly rapidly in the period since the Second World War. Among those areas to which archaeozoological research has extended essentially only in the past three decades, the Near East (South-west Asia with the southern part of Turkestan) seems to be the most interesting at the moment. There are several reasons. One is that the neolithic "revolution" or "transformation", whose essence was the switch from food gathering to food production, and whose one basic innovation was animal domestication, started in its most interesting and exciting form there. It is also important that the neolithic development of Europe was connected by numerous threads with the neolithic development of the Near East. From this viewpoint too it is especially important that both of the most important domestic species which determined the character of animal husbandry of the earliest Neolithic originated in the Near East.

Before discussing the problems of animal domestication in the Near East, it is useful to begin with a brief summary of the wild forms, their habitat and area of distribution.

The aurochs, the wild ancestor of cattle, spread over the whole Near East in the early post-Pleistocene period. Its remains occur in almost every neolithic sites of the area. The considerable size of these aurochs suggests that the geographical environment must have been favourable. When the plains and hills dried up and were reduced to steppes, the number of aurochs sharply diminished while small isolated populations developed which gradually died out. Around the time of Christ aurochs could be found only in inaccessible mountainous retreats. The typical habitat of the species was the forest steppe or the light forest. It was more an animal of the plains and hilly regions than the bison, its close relative, which was a good climber and preferred dense forests.

Wild sheep occur in abundance in the mountains of the whole Near East excluding the Levant. Their typical habitat is the mountains, though they also live on broad plateaux, climbing over 4,000 m above sea level in summer, and descending into the valleys in winter time.

The bezoar goat, the wild form of our domestic goats, lives all over the mountains from the Levant, through Anatolia, to the Hindu Kush. Its habitat is the high mountains with steep, rugged cliff facings and ravines.

The wild swine was widespread in the whole Near East, in marshy areas and near lakes and streams, in prehistoric times. It still lives in many regions there. It is an inhabitant of wet environments, preferring dense forest, but also living in the bush or among the bush or among the reeds along waterflows.

The wolf, the wild form of the domestic dog, is to be found all over the Near East and shows an extremely wide habitat tolerance that ranges from forest to desert and from mountains to plains.

The habitat preferences of the wild forms described above are a good key to determining in which environmental type of the Near East domestication took place. Steppe and desert can immediately be excluded, for the wolf was the only species which could live there (the dog had no important role in the prehistoric economy of the region). On the other hand, in mountains and their foothills all five species could be domesticated, and pig domestication could also take place in swampy areas of any geographical region.

The domestication of animals was by no means a sudden development, but was preceded by a man-animal relationship which went back hundreds and thousands of years. One must not forget that the relationship between the hunting man and the hunted animal was not simply the killing of the prey. Tens of thousands of hunter generations accumulated and passed on much information on the behaviour, anatomy, biology, physiology, and so on of wild animals, so that the domestication began on well prepared ground. Domestication was undoubtedly connected with a settled life, in common with other aspects of the neolithic revolution. Nevertheless, a settled life was not an indispensable precondition: domestication can happen (and in fact did happen) without settlements, more often however in extreme environmental conditions (for example, reindeer domestication of Arctic peoples), and in such cases real animal husbandry with a wide variety of domestic species never or rarely developed.

It is impossible to resolve the question of whether settled life made domestication possible or vice versa. Probably both are true: it is hardly conceivable that keeping and taming and subsequently breeding a larger number of captured wild animals could occur without corrals or stalls, necessitating at least temporary settled life. It is as inconceivable to supply food to a larger settled community without domestication and animal keeping or at least herding.

* Address: Archaeological Institute, Hungarian Academy of Sciences, 1250 Budapest 1, Hungary.

The primary stimulus for animal domestication was probably the drastic climatic and environmental change which followed the end of the Pleistocene. In the Near East the end of the Pleistocene was followed by a short dry period which ended at about 9000–7000 bc. The treeless, sagebrush (*Artemisia*) steppe developed with a trend toward present conditions. It is quite possible that the dry climate and the steppe–desert environment were the direct cause of the withdrawal of the rich wild mammal fauna to the well forested and well watered mountains. Man tried to follow his wild prey, but with the decrease in the number of wild mammals hunting itself became less and less successful. At the same time, man found wild cereals in the mountains and began first to collect and then to plant them. This activity would certainly have required the settlement of at least one part of the population, although the hunters could have continued their seasonal wanderings. It seems more likely, however, that the scale was reduced to a simple change from a summer camp to a winter one. In consequence, however, the wild fauna around the settlement would have thinned out, and man—either consciously or spontaneously—had to look for new sources of animal protein. He found them in animal domestication.

It is, however, quite clear that demographic pressure must also have played an essential part in the changes in food production. Other causes such as the political pressure of more developed groups, the attraction of the products of already food producing communities, and so on, were only of secondary importance in this respect.

Consequently the main aim of domestication was—failing proper methods of meat conservation—to secure living meat reserves. Earlier authors saw the main aim of domestication as the production of enough sacrificial animals to the different gods. Some of these authors have even divided the early domestic animals into groups indicating whether they were the sacrificial animals of the sun god or the moon goddess. This theory certainly does not bear closer investigation, although it is true that some of the domestic species were used for sacrificial purposes at a rather early date. For example cattle horns were found in the shrine of Çatal Hüyük in the fifth millennium bc¹, and at about the same time dog hams were sacrificed by the mesolithic population of Lepenski vir in the Iron Gate gorge of the Danube².

Domestication did not start in one single centre. As man arrived at a particular stage of cultural development at the same time in many areas, he began to control and domesticate certain animal species. Thus each species was domesticated at about the same time in different places and what is designated the earliest site of domestication of a given species can be a matter of sheer chance, depending on where archaeological research has been most successful. On the other hand domestication did not cease after the acquisition of the first domestic animals. It played an important part in increasing domestic stock during the whole Neolithic, it existed in the course of later prehistoric periods, it occasionally appeared even in classical and medieval times and new species are still being domesticated in certain areas of the world.

For a long time it was almost axiomatic that domestication started with the advent of the Neolithic. In more recent times, however, there has been increasing evidence that its earliest beginnings go as far back as the Mesolithic or even late Palaeolithic. In these earlier periods, however, only isolated attempts occurred, with the taming and keeping of individuals of one single animal species that—in spite of all their successes in the domestication of the species in question—never resulted in real animal husbandry exploitation of several domestic species. All these attempts had a common characteristic: their subject was either the dog or (more rarely) the pig. Such animals, whose food requirements were very similar to those of

man, survived on the remnants of human food and needed no substantial vegetable fodder. It was not by chance that in the time of these attempts at domestication plant cultivation did not yet exist, and the idea of securing such fodder therefore could not arise.

Domestication can be traced back to the final period of the Palaeolithic also in the Near East. Turnbull and Reed found domestic dog remains in the Zarzian (final Pleistocene) layer (about 12000 bc) of the Palegawra Cave in North-east Iraq³. Among them is a lower jaw whose crowded premolars prove the domesticated character of the Palegawra dog, making it the earliest known domestic animal. Otherwise in all probability domesticated dogs were found in Natufian (10000–8000 bc) sites of Palestine⁴.

The next two species of the neolithic domestic fauna were acquired at the beginning of the Neolithic, in the “era of incipient cultivation and domestication” (to use Braidwood’s terminology⁵). This era signalled the end of the food collecting phase, when man populated a wide variety of environmental zones and “utilised a far greater variety of resources within any given environmental niche” than before. Flannery calls it a “broad spectrum” collecting pattern⁶. This era lasted from about 9000 bc to about 7000 bc and resulted in the domestication of both small ruminants, the sheep and goat, of our domestic fauna.

The small ruminants were ideal subjects for the first experiments of man in domestication. First of all the capture of their domesticable young was comparatively simple, for the killing of adult individuals (which tried to protect their young) was much less dangerous than the killing of an aurochs cow or a wild sow. Besides this, as small animals of non-predatory character, they could be more easily handled, even after they became adult in captivity. Another important point was that their development was much faster than that of the large species, and man could therefore see the results of his experiments sooner. Finally the unexacting food requirements of both sheep and goat could be of most importance in the conditions of primitive animal husbandry.

During this time man attempted the control of other small ruminants too; first of all the different gazelles. Enormous numbers of gazelles lived in the Near East in prehistoric times, and even today great numbers of them are still killed. They often live in large herds, and the possession and rational hunting of such a large herd could easily supply even substantial settlements with enough meat. Probably this was the case with Jericho in Palestine whose 2,000–3,000 early neolithic inhabitants could hardly get enough meat from the very small domestic fauna of the settlement. On the other hand, the large number of gazelle bones found in the site suggest well regulated gazelle hunting or possibly herding. But although herding can verge on the brink of domestication it does not necessarily develop into a real animal husbandry. (This was the case with the gazelles, in which morphological changes which could be ascribed to domestication have never been seen.)

The earliest supposed domestication of sheep was described by Perkins in Zawi Chemi Shanidar, North-east Iraq from 10,870±300 yr BP (ref. 7). The sheep of Shanidar do not show any morphological changes, and their domesticated nature has been inferred from the high ratio (about 50%) of the animals killed while still immature, the sudden increase in the proportion of sheep in the fauna and finally the fact that the region of Shanidar is not considered the natural habitat of wild sheep.

It is appropriate to go over the evidence for domestication at this point because the same problems arise in every case of early domestication. The best evidence for domestication is the appearance of morphological changes (such as a decrease in size, changes in the body propor-

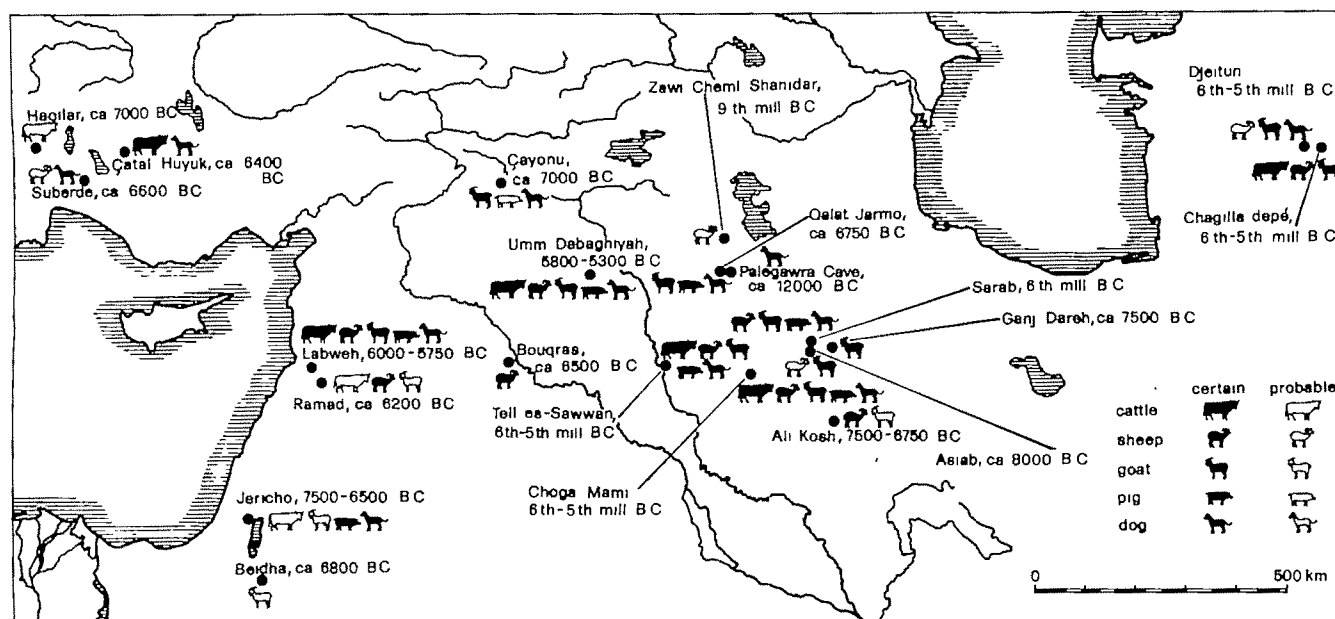

Fig. 1

tions and the form and fine structure of the bones, shortening of the skull, crowded or decreased teeth, hornlessness, changes in the horn form, and so on) in the animals. However, well defined morphological changes do not occur before about 30 generations, according to modern experiments on domestication. The length of a generation is 2–3 yr in small species (dog, sheep, goat, pig) and 5–6 yr in large species (cattle, horse, and so on). Since the earliest domestication of the first domestic species goes back as far as 8,000–14,000 yr, the delay of 60–90 or 150–180 yr in the occurrence of the morphological changes is hardly significant.

But there is indirect evidence of domestication which precedes the appearance of morphological change⁸. This evidence bears on the Near East, because the morphological differences between the wild and domestic forms of the ovicaprids, the most common species there, were not very well known even five years ago. In the late forties and early fifties the high ratio of immature animals alone was accepted as evidence of domestication in the Near East, but it is realised now that it can also be the result of certain hunting methods, and it is accepted as evidence only if it is corroborated by other data.

Further evidence of domestication is the high ratio of adult individuals and particularly of adult males among the remains of the wild form of a domestic species. The explanation is that in specialised hunting connected with domestication man first killed mature individuals, and tried to capture the young ones. At the same time the high ratio of killed males was due to the husbandry of the wild herd where man discovered early that fewer males than females are needed to keep the herd at a given level, and he therefore preferred to kill males if he needed meat.

Animal husbandry increases the occurrence of embryos and newborn animals and also tracks and excrement in settlements. Finally buildings and tools, equipment connected with animal keeping, and representations of domestication scenes of domestic animals, can also be very useful evidence.

Another possible occurrence of early domesticated sheep is in Asiab, West Iran, about 8000 bc (ref. 9). Morphological changes cannot be seen here either, but the very high ratio (80%) of mature animals and the exclusive occurrence of males in the wild sample suggest controlled hunting which might be connected with domestication. On the other hand, the excavation of Ali Kosh, again in

West Iran (7500–6750 bc) yielded remains of undoubtedly domesticated sheep, as well as the skull fragment of a hornless ewe¹⁰. (In prehistoric times there were no hornless individuals among wild sheep; such individuals appear only recently in small, isolated populations.) In the seventh millennium bc domestic sheep appear also in the northern Euphrates area (Bouqras, Ramad) and probably in Anatolia (Suberde) too¹¹.

The earliest domestic goats were found in Asiab, about 8000 bc¹². The occurrence of those domestic goats can be shown by anatomical changes (twisted horns) and the high ratios of mature (82%) and male (95%) individuals among the wild goats killed by the inhabitants. Just a little more recent is the appearance of the domestic goat at Ganj Dareh (7500 bc), in the immediate vicinity of Asiab¹³. The animal bone sample of this site has not yet been published in detail, but tracks found on the mud bricks of the site point to appearance of domestic goats in the settlement, since wild goats would surely not have come so close to human settlement. As for Ali Kosh, the occurrence of domestic goats in its earliest phase (7500–6750 bc) is uncertain, though probable¹⁴. The domestic goats of Jericho probably also originate from the eighth millennium bc (ref. 13). On the other hand, they can almost certainly be found all over the Near East.

The domestication of cattle and pig, the two latest species in neolithic animal husbandry, occurred during the seventh millennium bc¹⁵. In this era, villages produced most of their food, though hunting and gathering were still important in certain areas. This era began at the end of Prepottery Neolithic and grew into early Pottery Neolithic.

The earliest positively domesticated pigs in the Near East were found in Qalat Jarmo, about 6750 bc (ref. 15). They were fully developed domestic animals with well defined morphological changes. Since there are no traces of a local domestication in the site, one must suppose that they got there from another site where pig domestication took place earlier. The occurrence of domestic pigs is only probable in Çayönü, Anatolia (7000 bc)¹⁶ but it is certain in the early levels of Jericho¹⁷.

The earliest domestic cattle of the Near East are from Catal Huyuk, Anatolia (6400 bc)¹⁸. Some of the cattle bones of the aceramic level of Hacilar, Anatolia (7000 bc) may also be from domesticated animals (they seem to be smaller than the aurochs bones) but it is still uncertain because of the small sample size¹⁹. The occurrence of

domestic cattle in the pre-ceramic phase of Jericho is also not entirely certain¹⁷.

The above descriptions clearly demonstrate that man had completed the domestication of all five species characteristic of neolithic animal husbandry in the Near East by the middle of the seventh millennium BC. On the other hand, it is interesting that the five species did not appear together in any site in the area before the end of the seventh millennium BC, although many different species combinations occurred on many sites. What is particularly curious is that the same five species could be found in several pre-ceramic sites of the Greek islands and mainland Greece around the middle of the seventh millennium BC¹⁸⁻²⁰. This occurred in spite of the fact that out of the five species two (sheep and goat) could not be domesticated on the European mainland because of the absence of wild forms, while two others (dog and pig) were domesticated in the Near East earlier than in South-east Europe. With only one (cattle) does European domestication seem to precede the Near Eastern, although with such a slight time difference (the radiocarbon date of Argissa Magula, Thessaly is 100 years older than that of Catal Hüyük, Anatolia) that one cannot be sure. Nevertheless, the final word has not yet been spoken on this question because animal bone samples from the pre-ceramic West Anatolia have not yet been published. This region shows the closest genetic connections with the earliest Neolithic of South-east Europe.

As mentioned above, animal husbandry embracing all five domestic species developed in the Near East at the end of the seventh millennium and became widespread during the sixth millennium BC. From this period the faunas of several sites are known, for example Labweh from Lebanon, Umm Dabaghiya, Tell es-Sawwan and Choga Mami from Iraq, Sarab²¹ and Tepé Sabz¹⁰ from Iran, Djeitun and Chagilla depe²² from Turkmenistan. Their common characteristic is that the caprovines occur as an overwhelming majority in them; the ratios of the other domestic species are rather variable. The ratios of sheep and goat were determined by the geographical environment: in mountainous regions the goat was more common, on plains and among hills the sheep were in the majority. In the settlements of this period also the importance of animal husbandry relative to hunting was quite variable. In general, animal husbandry was more important, but in certain areas hunting remained of decisive importance. In such cases it took a specialised form, such as in Sarab where it was connected with goat domestication, or as in Umm Dabaghiya without local domestication. This latter site is particularly important because, in spite of the fact that its inhabitants kept all five neolithic domestic species, the importance of animal husbandry was minimal, the remains of domestic animals comprising only 10-12% of the animal bone sample. The hunting was specialised for the half-ass (onager) and its bones represent nearly 70% of the sample. This overspecialised hunting did not, however, lead to onager domestication.

The neolithic domestic fauna did not change much even in the further course of the period, and only the sheep gained more ground against the goat. On the other hand, the importance of animal husbandry grew at the expense of hunting which generally declined after the fifth millennium BC. In the third to fourth millennia, the horse and the ass joined a domestic fauna that was gradually completed by new species later, none of which, however, endangered the leading position of the caprovines.

Concerning the early domestic animals of the Near East one may reasonably ask what use they were to neolithic man. As already hinted their original use was almost exclusively for meat. The fact that the first domesticated animals—with the exception of the dog—were derived from species which were originally hunted for their meat has obvious implications. Furthermore, early neolithic man killed most of his domestic animals at an immature age, for example,

caprovines before the first or second winter. The reason was not only that the meat of young animals was more palatable but also that man could provide fodder only for a small, precious breeding stock in the winter fodder shortage. In the advent of domestication and animal husbandry man ate the flesh of every domestic species including the dog whose skulls with opened brain-case (brain was considered a delicacy even in those times) can often be found in the garbage pits of settlements up to the Bronze Age²³. Man did not cease to eat dog meat until the end of the Bronze Age—probably the earliest food prohibition in the world.

The secondary use of hide or fur, tendons, intestines, bones and so on, for tools and clothes was probably established quite early. Only the dog, however, had secondary uses as a live animal, in the roles of hunting companion, watch-dog and herd-dog. In the European Mesolithic it was also used as a sacrificial animal²⁴, although this is not yet proven for the Near East. On the other hand, cattle sacrifices in the Near East have very ancient origins. In the shrine of Catal Hüyük both aurochs and cattle horn-cores were found embedded into clay animal heads²⁵, while the bull cult goes back as far as the sixth millennium BC²⁶.

Among real secondary uses of live animals probably milking was the earliest. Animals at a primitive stage of domestication had obviously only enough milk for feeding their young, although they could be milked if their young died or were slaughtered. As prehistoric bone samples witness, death of the young animals was not rare in early animal husbandry, and the young were probably slaughtered so that the suckler animals could be milked (this might also account for the high ratio of animals killed as juveniles in prehistoric settlements). Later, enough milk was produced to give a surplus for human consumption. It is obviously difficult to demonstrate milking from prehistoric material. The earliest representation of milking and milk processing is known from a frieze of the Nin-Hursag temple in Ur (after 2400 BC)²⁷. Interestingly enough the cows are being milked in this scene from the rear, as is usual with goats. From this one may infer that the milking of cows may have emerged after the milking of goats.

Another early secondary use was that of wool of sheep. The body of the wild sheep is covered by coarse kemp among which wool fibres appear only in winter time. These wool fibres are, however, very short and straight. Long, curly wool fibres which do not undergo yearly changes appeared apparently as a result of sudden mutation after domestication. This mutation probably occurred rather early, to judge from a clay sheep statuette found in Sarab (sixth millennium BC)²⁸ on which the artist has depicted very skilfully the curliness of the wool. Such representations became very common from the fourth millennium BC on, and clay tablets from the turn of the third and second millennium BC often gave sheep shearing lists from estates of Old-Babylonian temples²⁹.

It is still not known how far back the use of draft power of cattle goes. Since there are osteological data in this respect from the Neolithic of South-east Europe, however, one can assume the same too on the Near East. Wheeled vehicles appeared there in the fourth to third millennium BC and they were drawn by cattle. In view of the highly developed state of agriculture in Mesopotamia, cattle-drawn ploughs or some kind of unwheeled vehicle (travois, sledge) could easily have occurred.

The development of early animal husbandry came to an end in the third millennium BC, and at the turn of the third and second millennia, a qualitative change took place. A switchover started from primitive animal keeping to selective conscious animal breeding. This happened on the estates of temples first and first concerned only wool-bearing sheep but later extended slowly to other species as well. As a result of this the size and production of domestic animals grew, their body proportions changed, and new breeds developed which reached remote regions in a short

time and exerted an influence on the domestic animals and animal husbandry as a whole.

Retrogression rate of the Victoria Falls and the Batoka Gorge

R. M. Derricourt

National Monuments Commission, PO Box 124, Livingstone, Zambia

From an analysis of the archaeological dates for deposits in the Victoria Falls area, we suggest that the rate of erosion of the Victoria Falls was somewhat slower than previously assumed.

ATTENTION was first drawn in the pages of *Nature* in 1905 (ref. 1) to the evidence for the late date and relatively fast rate at which the line of the Victoria Falls, straddling the Zambezi river between Zambia and Rhodesia, reached its present position. In spite of initial challenges, the view was confirmed by subsequent geological and archaeological studies^{2,3} that the gravels now isolated from 110 m to >250 m above the river were laid down by the Zambezi before and during the gradual retrogression of the falls.

The successive positions of the line of the falls are considered to have followed zones of close jointing which formed belts of weakness in the basalt bedrock. These formed steep sided gorges, visible for ~111 km downstream from the Victoria Falls. The archaeological contents of these river-laid deposits above the gorges, or of deposits and events considered to be contemporary, have been used to determine the date by which the falls line had reached different positions⁴, and thus to calculate the speed of retrogression. There are clearly limits to the reliance that can be given to the geological dating of deposits by their archaeological contents, even where these do not seem to be redeposited. In the absence of much needed new geomorphological studies, however, the archaeology remains our best source of dating evidence. The speeds of retrogression previously calculated^{4,5} gave figures which are equivalent to rates of regression between 3,380 and 5,930 yr km⁻¹.

Such a fast rate of retrogression contrasts with the subjective impression of stability of the falls gained by residents

and visitors. While rock fall is very infrequently observed at the falls line itself, in spite of a mean annual water flow of $3.6 \times 10^9 \text{ m}^3 \text{ yr}^{-1}$, it seems no greater at the line of the western end of the falls, which has been identified⁶ as the beginning of the next line of falls.

The rate of erosion of the gorges was not constant, because of the variable section of the channel in the gorges, and the climatic variation of rainfall in the basin of the upper Zambezi in eastern Angola, western Zambia and northern Botswana. A mean post-Pleistocene rate of 0.29 m yr⁻¹, which could be derived from suggestions⁷ for the date of the erosion of the upper gorges, would, however, seem to require more visible modern erosion.

An empirical test may be made from a generally very accurate topographical illustration by Thomas Baines who visited the falls in 1862. One of his paintings⁷ shows the beginning of the 'new gorge' from the position of the western end of the first gorge. Comparison with the present condition suggests erosion here could not have been more than a few metres in over a century. The view shown represents what today⁸ is a stretch of ~75 m.

Recent reassessments of the dating of Stone Age industries of Southern Africa suggest that the dating of the retrogression of the Victoria Falls based on such industries can now also be reconsidered.

The upper gorges

The date of the erosion of the Fourth Gorge is considered⁹ to follow the Middle Stone Age occupation of the area. The Kalahari Sand II, actually redeposited Kalahari Sands laid down in a dry period, overlies river-bed gravel to the south of the Fourth Gorge, but not further upstream. This sand, contemporary with what was formerly called the 'Rhodesian Magosian' industry, was laid down before the erosion of the upper three gorges.

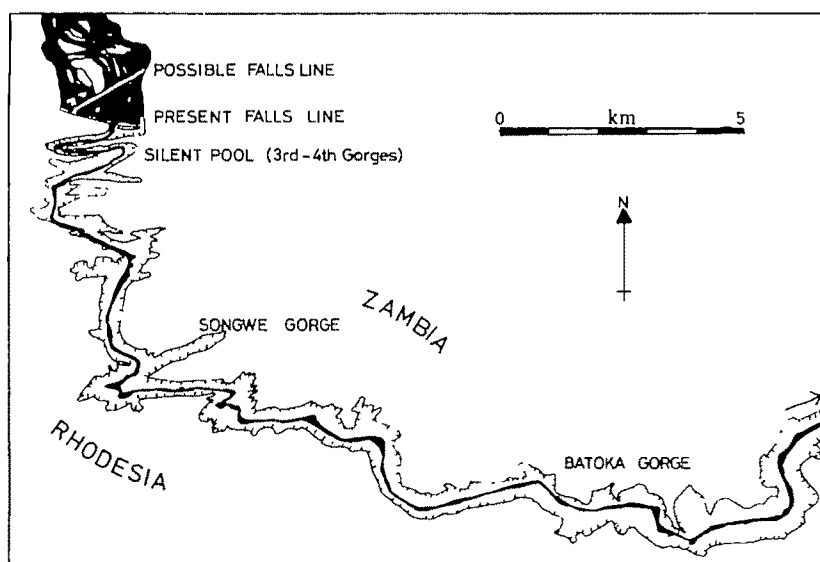

Fig. 1. Map of the falls area.

The distance from the Silent Pool, where the fourth gorge meets the third gorge, to the present day falls is 2.96 km (ref. 8) while the distance from the exit of the second gorge into the falls line to the beginning of the projected new gorge at the western end of the falls is a further 1.17 km, a total of 4.13 km linear retrogression. Estimates of the rate of retrogression have used the north-south erosion following the river, but not the easier lines of erosion which transect this line, and we can therefore use the figure of 2.96 km.

The dates of Magosian and related industries have been reassessed recently. They can no longer be seen as late or terminal Pleistocene cultures making the transition of Middle to Later Stone Age, but rather a long term tradition partly contemporary with other Middle Stone Age industrial traditions⁹. Sites attributed to the Magosian complex and related industries in South Africa have been ¹⁴C dated¹⁰, from $>44,500$ to $>50,250$ yr b.p. at Rose Cottage Cave, and $45,900 \pm 2,100$ yr b.p. at Montagu Cave, but with other dates at the end of the Pleistocene⁸. In Rhodesia dates for Magosian-related material may be later; Pomongwe has a date of $15,800 \pm 200$ yr b.p. Finds in Zambia which have been grouped with those from the Kalahari Sands II¹¹ include assemblages of 'Proto' Later Stone Age¹² from Leopards Hill dated between $23,800 \pm 360$ yr b.p. and $21,550 \pm 950$ yr b.p. Apparently contemporary is the 'Pre-Later Stone Age' industry at Kalembo in eastern Zambia¹³ dated to 24,600 yr b.p. and 24,420 yr b.p., it is succeeded by a Later Stone Age industry dated to at least $15,330 \pm 1,100$ yr b.p., while a similar industry at Leopards Hill is dated to $16,715 \pm 95$ yr b.p.

At Kalambo Falls in northern Zambia a Magosian-related industry named the Polungu¹⁴ has been dated by J. D. Clark at more than $9,550 \pm 210$ yr b.p., possibly as old as 20,000 yr b.p., or even, by comparison with finds at Zombepata Cave¹⁵ some 20,000 yr earlier than that. At Kalambo Falls, however, an earlier industry of Lupembian type has been dated at $31,660 \pm 600$ yr b.p., but this date seems younger than should be expected on other grounds; a date over 70,000 yr b.p. for most of the Lupembian may be more probable (K. W. Butzer, personal communication).

Present evidence would suggest the demise of Magosian and related industries in most of Zambia and Rhodesia was considerably earlier than the end Pleistocene date of 12,000 b.p. previously assumed. The most likely time is between 21,000 and 17,000 b.p. with an origin for the complex in the area between 25,000 b.p. and 30,000 b.p. There is as

yet little to support for Zambia or for Rhodesia¹⁰ a date similar to the estimate for South Africa^{10,17} that the Later Stone Age began at $\sim 35,000$ –20,000 yr b.p. The question of such a date will probably become less conflicting when more detailed study has been carried out on the nature of the industries in the 40,000–12,000 yr b.p. range.

The Kalahari Sands II which predate the erosion of the last 2.96 km of gorge, are therefore dateable to a dry phase within the period defined for the Magosian, at the outside 30,000–17,000 yr b.p., and more probably 30,000–20,000 yr b.p.

Correlated rock falls in Rhodesian caves with archaeological deposits¹⁸ suggest there was a wet period following the end of the 'Stillbay' phase of the Middle Stone Age, and dated at between 25,000 and 21,000 yr b.p. It was followed by a dry phase in which the local variant of the Magosian flourished, a period one can correlate with the Kalahari Sands II of the Victoria Falls, which would thus be dated at later than 25,000 yr b.p. Palaeoclimatic studies at Kalambo Falls¹⁸ suggested close correlation of the temperature curve with that of Europe during late Pleistocene and post-Pleistocene times but the rainfall pattern need not be correlated with temperature change.

Accepting the suggested date limits for the Zambian industries related to the Magosian, and the Rhodesian rock fall, a date for the deposition of the Kalahari Sands II would be between 25,000 and 17,000 yr b.p.

If we place the termination of the Zambian Middle Stone Age at the same time as that now suggested for South Africa, this would allow 20,000 b.p. as a possible date for the start of the erosion of the third gorge, or a mean rate of $6,760 \text{ yr km}^{-1}$ (0.15 m yr^{-1}).

The Zambezi to Songwe Gorge

The dating of the gorges below this point relates to the Younger Gravels and associated earlier deposits attributed to the Upper Pleistocene. The younger gravels themselves contain derived Early Stone Age material and less abraded material from the beginning of the Middle Stone Age, formerly called 'Proto-Stillbay'. The overlying sands and calcretes have a 'Stillbay' industry. Such younger gravels are found at least as far as the top of the gorge above the confluence of the Songwe river with the Zambezi, some 6.75 km below the turn of the fourth gorge into the third, measured along the line of the modern river.

The Younger Gravels were claimed to have been laid

down in a period of high rainfall originally identified with the 'Third Pluvial'.

The river above Songwe Gorge must have eroded back since the period of high rainfall and earlier Middle Stone Age^{4,5}; this period had previously been estimated as within the past 50,000–40,000 yr.

The beginning of the Middle Stone Age in Southern Africa has been suggested at ~100,000 yr b.p. (ref. 10) and perhaps over 130,000 yr b.p. as indicated by recent work (K. W. Butzer, personal communication). At Nelson Bay Cave on the Southern Cape coast of South Africa, the Middle Stone Age extended back into the Eem Interglacial probably before 75,000 b.p. (refs 19, 20) and very possibly before 125,000 yr b.p. (K. W. Butzer, personal communication).

The earliest Middle Stone Age radiocarbon date for Zambia is $31,660 \pm 600$ yr b.p. at Kalambo Falls, although the preceding Sangoan was originally dated only six centuries before¹⁴, with an early date of 46,100 yr b.p. Other forms of dating contrast with this picture. This is especially true of the finds of Broken Hill Man at Kabwe in central Zambia. Amino acid racemisation dates for human and associated animal bones at Broken Hill suggest a date of ~110,000 yr BC for Broken Hill Man^{11,22}. Klein²³ argues that the faunal remains probably associated with Broken Hill Man must fall within the Eem Interglacial, or in the Middle Pleistocene (which would imply an earlier date).

The archaeological associations with these dates are unfortunately not completely clear. At the time of Clark's classic study of the Stone Age cultures of the Zambezi valley, however, he attributed³ the finds with Broken Hill Man to 'Proto-Stillbay', and thus a parallel is suggested—whatever terminology be accepted today—between the Broken Hill finds and those of the Younger Gravels. Subsequent reassessment, however, suggests²² the associations may be Sangoan.

The 'Proto-Stillbay' industry was seen as derivative from Sangoan in the Victoria Falls area. It seems, however, that Sangoan industries in southern Africa as a whole overlapped with the earliest Middle Stone Age⁹. The Sangoan at Kalambo Falls was dated by radiocarbon between 46,100 and >32,600 yr b.p., and the preceding Acheulian between >35,000 and $61,700 \pm 1,300$ yr b.p. but these dates now seem much too late. A new minimum date from amino-acid racemisation of >110,000 b.p. (ref. 24) for the Acheulian of the site suggests all the earlier dates for Zambia need to be held in some uncertainty, and probably accepted as *termini ante quos*. The early Middle Stone Age industry of the Younger Gravels at Victoria Falls, which derives from a Sangoan industry, cannot be dated later than 40,000 yr b.p. while in the light of the new dating evidence, a date of <130,000 yr b.p. seems acceptable.

Correlation with the Broken Hill bones and artefacts would suggest a date at ~110,000 yr b.p. for the artefacts of the Younger Gravels. The geological chronology from the southern African coast¹⁹ suggests that the main wet period within the range of the early Middle Stone Age in that area was in the Eem Interglacial before 75,000 yr b.p. Correlations of coastal and inland rainfall patterns are not necessarily reliable, and it may therefore be more useful to rely on the cultural data. Since the erosion above the Songwe Gorge is subsequent to the earlier Middle Stone Age settlement, the falls may have taken up to 90,000 yr to cut back the 6.75 km from the Songwe river to the third gorge, a maximum rate of $13,330 \text{ yr km}^{-1}$ or an average of $11,280 \text{ yr km}^{-1}$ for the past 110,000 yr.

If the retrogression of the stretch from Songwe Gorge were taken to follow the end of the Interglacial, at 75,000 yr b.p., the rate from Songwe to the fourth gorge would be $8,150 \text{ yr km}^{-1}$; an average for the whole distance of $7,725 \text{ yr km}^{-1}$. These alternatives correspond to an average rate of 0.09 or 0.13 m yr⁻¹.

The lower gorges

The area of the gorges below Songwe Gorge has poor access and has not been studied in any detail. The gorges extend ~101 km measured along the river, from the Songwe river to their limit above the confluence with the Matetsi, and the dating of the erosion of this stretch of river is hard to determine. Clark³ originally considered that the gorge, perhaps to 6 km above Ohimamba Rapids (a distance that can be calculated at 31 km along the river) was eroded in the Upper Pleistocene, while the lower gorges (70 km) were eroded in the Middle Pleistocene; but a Lower Pleistocene date for the lowest part of the gorges was subsequently suggested⁴. There seems little direct geological evidence for this, and no archaeological data is yet available for the area, although further fieldwork would be useful.

The Middle Pleistocene is now dated²⁸ from 700,000 to 130,000 yr b.p. If we adopt the alternative rates calculated for the retrogression from Songwe Gorge to the modern falls line in the last 75,000 or 110,000 yr, the erosion of the remaining 31 km of the stretch above Chimamba Rapids would have taken 240,000–350,000 years, since 315,000–460,000 yr b.p., well within the Middle Pleistocene.

The presence of Older Gravels of possibly early Middle Pleistocene date near the Matetsi confluence at the lower end of the whole gorge suggests a Lower Pleistocene date for the beginning of the falls retrogression. It seems likely that the erosion of the gorge above the Chimamba Rapids was much more recent than the lower stretch of 70 km (ref. 3), and the geomorphology of the slope and the available evidence on river-laid deposits for this stretch suggests a possible chronological break between the erosion of the lower 70 km and the upper stretch. It is tempting to suggest that this break may have been in the early Middle Pleistocene. The lower stretch from the Matetsi confluence above the Chimamba Rapids, which has geomorphological unity, could all have been eroded within the Lower Pleistocene, over a period (calculated from the rates for the upper stretch) between 540,000 and 790,000 yr since at least 1.25×10^6 yr b.p., an average of 0.9 m yr^{-1} .

In the absence of well dated contemporary sequences in the region, archaeological dating of the geological events can only be tentative and more detailed geomorphological studies, especially on the lower gorges of the Zambezi, would do much to clarify the situation.

I would like to thank Dr K. W. Butzer for comments, criticism and information.

Transformation by murine and feline sarcoma viruses specifically blocks binding of epidermal growth factor to cells

George J. Todaro & Joseph E. De Larco

Laboratory of Viral Carcinogenesis, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20014

Stanley Cohen

Department of Biochemistry, Vanderbilt University, Nashville, Tennessee 37203

Normal cells in culture have membrane receptors for epidermal growth factor (EGF); EGF stimulates cells to divide by binding to these receptors. Cells transformed by murine and feline sarcoma viruses rapidly lose the ability to bind EGF, whereas cells transformed by the DNA tumour viruses, polyoma and SV40, or infected with non-transforming RNA tumour viruses have normal levels of functional EGF receptors. The results suggest that a product of the sarcoma virus genome specifically changes cell EGF receptors; the sarcoma gene product may, then, be functionally related to EGF.

RNA-containing mammalian and avian sarcoma viruses (type C viruses) can produce tumours in a wide variety of susceptible animal hosts and can transform cells from a number of different species in tissue culture^{1,2}. Genetic analyses using temperature-sensitive mutants³ have distinguished specific viral genes (sarcoma genes or oncogenes^{4,5}) essential for transformation. The genomes of the sarcoma viruses contain specific RNA sequences⁶⁻⁸ which are not found in transformation-defective type C viruses. The sarcoma-specific information could code for a protein with a maximum molecular weight of 30,000–40,000. The sarcoma gene product, however, has not been identified; it is presumably synthesised in small quantities and is biologically highly potent. Sequences related to the sarcoma-specific genes have, however, been found as normal constituents of the cellular DNA of both birds⁹ and mammals^{10,11}. From these considerations, we would suggest that the product of the genes should be related to or identical with a normal cellular gene product and that such a protein is (1) a regulator of cell proliferation, (2) of low molecular weight, (3) evolutionarily conserved, (4) produced in only small quantities by sarcoma virus-transformed cells, and (5) synthesised by some normal cells which have not been infected by sarcoma viruses.

One protein that satisfies the criteria for a possible oncogene product is epidermal growth factor (EGF). Mouse epidermal growth factor has 53 amino acids and a molecular weight of 6,045 (ref. 12). It will stimulate the proliferation of various epidermal and mesodermal cells in both whole animals and tissue culture. Injection into neonatal mice accelerates the time of eyelid opening and tooth bud eruption^{13,14}. In organ culture EGF stimulates the growth of epithelial, corneal and mammary gland cells¹⁴⁻¹⁶ and in tissue culture it stimulates cell division of mouse cell lines such as 3T3 and BALB/3T3^{17,18}, mouse and human diploid fibroblasts^{13,19} and human glial cells²⁰. As little as 0.1 ng ml⁻¹ of EGF will stimulate DNA synthesis in human fibroblasts²¹. A closely related protein (human EGF) has also been puri-

fied from human urine and shown to have all the biological properties of mouse EGF^{21,22}.

The primary event in growth stimulation induced by EGF (as with other polypeptide hormones²³) is the binding of EGF to specific cell membrane receptors^{24,25}. The factors from both species utilise the same set of membrane receptors in a wide variety of vertebrate cells for their growth stimulatory effects²¹. The genes for both EGF production and its membrane receptors, therefore, seem to have been well conserved in evolution, although the precise normal physiological function of this growth regulatory system is not fully understood.

We now report that in several cell culture systems transformation by mouse and feline sarcoma viruses produces a rapid and profound loss of detectable membrane receptors for EGF. This is not seen in cells transformed by the DNA viruses, SV40 and polyoma, or in cells producing non-transforming leukaemia viruses.

Mouse EGF binding and transformation

Table 1 shows the binding of ¹²⁵I-labelled EGF to various normal and transformed cells in tissue culture. Three different clonal systems of mouse cells were available for study—random bred Swiss 3T3 (ref. 26), BALB/c 3T3 (ref. 27), and NIH Swiss 3T3 (ref. 28). Clonal lines of parental cells were compared with transformed clones produced either by DNA-containing viruses or by RNA-containing viruses. Cells were assayed in their log phase of growth when they were actively dividing, 24–48 h after seeding subconfluent cultures. In each mouse cell system, the Moloney sarcoma virus-transformed cells²⁹ as well as the Kirsten sarcoma virus-transformed cells³⁰ were much less able to bind labelled EGF. One Rous sarcoma virus-transformed BALB/3T3 clone (B77-A31 clone 1) showed only a slightly reduced level of binding compared with normal cells and was quite different in this respect from the MSV-transformed cells.

The 3T3 cell line has been shown to be susceptible to transformation by two DNA tumour viruses, polyoma and SV40 (ref. 31), and, further, doubly transformed clones of 3T3 could be obtained that had integrated both SV40 and polyoma genomes^{32,33}. These cells have all the *in vitro* properties associated with viral transformation and produce tumours in susceptible animal hosts. Whereas MSV-transformed 3T3 clones bind very little labelled EGF the DNA virus-transformed cells show levels of binding not significantly different from the parental cells (Table 1).

When cell lines derived from rat (NRK cells³⁴), mink (Mv1Lu cells³⁵), and cat (FFc60WF³⁶) were studied, cells transformed by the murine sarcoma viruses again showed greatly reduced binding of labelled EGF (Table 1). The normal mink kidney cells, an epithelial line, bound approximately 3–5 times more labelled EGF than did 3T3,

The binding assays were performed on subconfluent cell culture monolayers in 60-mm Petri dishes (Falcon 3002). Approximately 1×10^6 cells per dish were seeded in Dulbecco's modified Eagle's medium (DMEM) containing 10% calf serum 24 h before binding ^{125}I -EGF. The cells were washed twice with 2-ml aliquots of binding buffer which consists of DMEM containing 1 mg ml $^{-1}$ bovine serum albumin (BSA) and 50 mM *N,N*-bis-(2-hydroxyethyl)-2-aminoethanesulphonic acid (BES), adjusted to pH 6.8. Binding was performed using 3 ng of ^{125}I -labelled mouse EGF (containing approximately 110,000 c.p.m.) in 1.5 ml of binding buffer. After incubation for 40 min at 37 °C, unbound ^{125}I -EGF was removed and the cells washed four times with 2-ml aliquots of cold binding buffer. The cells were solubilised in 0.75 ml of lysing buffer, composed of 0.01 M Tris-HCl, pH 7.4, containing 0.5% sodium dodecyl sulphate and 1 mM EDTA, and the contents transferred to a counting vial. The dishes were washed two more times with 0.5-ml portions of lysing buffer, the contents transferred to the counting vial, and the radioactivity determined using a Beckman 300 series gamma counter. Nonspecific binding was estimated by determining the amount of cell-bound radioactivity in the presence of 10 μg of unlabelled mouse EGF. All data given have been corrected for nonspecific binding. In a typical experiment where 10^6 c.p.m. of ^{125}I -EGF was added, the values for nonspecific binding range from 50–150 c.p.m. above machine background. To test for the possibility that the sarcoma virus-transformed cells rapidly degrade the labelled EGF by proteolytic action, normal and transformed cells were cocultivated in varying ratios and assayed for EGF binding. The binding to normal cells was independent of the number of K-NRK cells present even at a 50-fold excess of transformed cells (2×10^6 normal cells to 1×10^6 transformed cells). When ^{125}I -labelled EGF was first incubated with transformed cells for 60 min and then transferred to normal cells it bound with the same efficiency as freshly-added EGF; no significant degradation of EGF by the transformed cells could be detected.

NRK or cat cells. Although the transformed mink cells bound detectable quantities of labelled EGF, considerably less polypeptide was bound by transformed clones compared with the normal cells (85–95% reduction). Feline sarcoma virus, FeSV (Gardner-Arnstein strain²⁷), transforms the rat, mink and cat cells; non-producer transformed clones have been obtained in all three systems (unpublished).

Cells transformed by FeSV also showed greatly reduced EGF binding, similar to the levels of binding seen with cells transformed by the murine sarcoma viruses. A clone of NRK transformed by avian sarcoma virus (Schmidt-Ruppin strain) showed more nearly normal levels of EGF binding. Reduction in EGF binding to cells derived from several mammalian species is evident after infection by

Table 2 Binding of human ^{125}I -EGF to normal and virus-transformed cells

Cell line	Transformed by	Designation	Binding ^{125}I (c.p.m. per 10^6 cells)
BALB/3T3	None	A31	3,100
	MSV-Moloney	M-A31-CL71	300
	MSV-Kirsten	K-A31-CL234	110
	SV40	SV-A31-CL1	6,800
	SV40	SV-A31-CL6	4,300
NRK	None	NRK-CL2	7,900
	MSV-Moloney	M-NRK-CL537	70
	MSV-Kirsten	K-NRK-CL1	10
	FSV-Gardner	FSV-NRK-CL3	190
Mink lung	None	Mv1Lu (CCL 64)	24,500
	MSV-Kirsten	K-MSV-64-CLJ1	1,300
	FSV-Gardner	FSV-64-CL2	900

The binding assays were similar to those described in Table 1 except that ^{125}I -labelled human EGF (1.2 ng, 63,100 c.p.m.) was used instead of ^{125}I -labelled mouse EGF. Ten micrograms of unlabelled mouse EGF were used as controls for these experiments. As in Table 1 the nonspecific binding was 50–150 c.p.m. above the counter background.

MSV and FeSV, but not by avian sarcoma viruses or transforming DNA viruses.

The replication of non-transforming type C leukaemia viruses does not affect the ability of cells to bind EGF. Both BALB/3T3 (clone A31) and NIH Swiss 3T3 cells infected with MuLV (Rauscher strain) bind as much ^{125}I -labelled EGF as uninfected cells. Similarly, mink kidney cells infected with feline leukaemia virus²⁷ or with endogenous baboon virus^{28,29} show no reduction in EGF binding (data not shown). Clonal lines of mouse and rat cells such as subclones of A31-7 and NRK clone 2 that can spontaneously produce endogenous type C viruses also bind ^{125}I -EGF as effectively as their parental cell counterparts.

Fig. 1 Time course for the binding of ^{125}I -mouse EGF to normal and transformed cells. The binding buffer consists of Dulbecco's modified Eagle's medium (DMEM) containing 1 mg ml^{-1} of BSA and 50 mM N,N -bis-(2-hydroxyethyl)-2-aminoethanesulphonic acid (BES), pH 6.8. The bindings were carried out on cell monolayers in 60-mm plastic Falcon Petri dishes after washing the plates twice with 1.5 ml of binding buffer. The bindings were then started by the addition of 1.5 ml of binding buffer containing 15 ng of ^{125}I -mouse EGF ($5 \times 10^6\text{ c.p.m.}$) and incubated at 37°C for the stated periods. At the end of the incubations the binding buffer containing the unbound ^{125}I -EGF was removed and the cell monolayers were washed four times with cold binding buffer to remove the excess unbound ^{125}I -EGF. The amount of ^{125}I -EGF bound to the cellular monolayers was measured by lysing the cells and determining the radioactivity present in the lysate. *a*, Binding to normal rat kidney cells: the untransformed parent (Δ), NRK (6.0×10^5 cells per dish) and the Kirsten sarcoma-transformed cell (\circ), K-NRK CL1 (8.5×10^5 cells per dish). *b*, Mink cells: the normal parent (Δ), MvLu (4.5×10^5 cells per dish) and the Kirsten sarcoma-transformed cell (\bullet), K-MSV-64 CL1 (5.5×10^5 cells per dish).

Human EGF binding

An epidermal growth factor has been isolated from human urine which shows biological properties similar to those of mouse EGF^{21,22}. Table 2 shows that human EGF also readily detects the difference between MSV-transformed cells, normal cells and SV40-transformed cells. Like mouse EGF, more human EGF binds to the mink lung cells than to BALB/c 3T3 cells and NRK cells. Antisera to mouse EGF cross reacts only weakly with human EGF, and likewise antisera to human EGF cross reacts quite poorly with mouse EGF⁴⁰. Nevertheless, both mouse and human EGF can compete equally well with each other in the binding assays used here with mouse, rat and mink cells, suggesting that the biologically active portion of the molecule involved in binding to receptors has been more conserved during evolution than the major antigenic determinants recognised by antibodies prepared to the mouse and the human EGF.

Time course of EGF binding

Figure 1a shows the extent of binding of labelled mouse EGF to NRK cells, and to NRK cells transformed by murine sarcoma virus, as a function of the time of addition of labelled polypeptide. Maximal binding is achieved for NRK cells at 90 min, after which there is small decline in the EGF bound. This decline is not seen when the binding assays are performed at 23°C rather than 37°C . At no time during the 3-h incubation period at either temperature (in some experiments incubations have been run for as long as 5 h) is there any significant binding of EGF to the sarcoma virus-transformed rat cells. With mink kidney cells (Figure 1b), the time course is slightly different, with peak binding reached earlier, at 40 min, followed by a slight decline. With the transformed mink cells, however, there is a low level of EGF binding, again reaching saturation at 40 min. The transformed mink cells retain some receptors capable of binding EGF even after MSV transformation whereas, with rat and mouse cells, binding is almost entirely abrogated by MSV transformation.

To study the effect of EGF concentration on binding, an experiment was performed using increasing quantities of unlabelled EGF (up to 670 ng of EGF per 10^6 cells) together with the ^{125}I -labelled polypeptide (Fig. 2). No significant binding to the transformed NRK cells was seen at any concentration tested (data not shown). The final extent of binding to mink cells was maximal at approximately 850 pg bound per 10^6 cells for the normal mink cells and 8 to 9 times less for the transformed mink cells. Using this data to obtain a Scatchard plot, recognising that the system is not in complete equilibrium, we calculated that there are 8.4×10^4 receptors per normal mink cell and only 1.0×10^4 receptors per cell in the transformed mink clone. Detectable levels of binding to receptor sites on the transformed and normal cells can be completely inhibited by the addition of unlabelled EGF. Thus, with each of the

Fig. 2 Effect of EGF concentration on binding to normal and transformed mink kidney cells. Three nanograms of ^{125}I -EGF ($210,000\text{ c.p.m.}$) were used in each assay, and unlabelled EGF was added to bring the total EGF to the indicated concentrations. The specific binding was determined after a 40-min incubation at 37°C . Δ , Untransformed MvLu; \circ , Kirsten sarcoma virus-transformed progeny K-MSV-64 CL1.

Table 3 Specificity of binding of ^{125}I -EGF to sarcoma virus-transformed cells

Mouse	Cell line	^{125}I (c.p.m. bound per 10^6 cells)		
		EGF	gp70	Con A
	BALB/3T3 untransformed	6,700	2,040	59,500
	MuLV infected	7,400	40	NT
	Sarcoma virus-transformed, virus-producer	170	30	NT
	Sarcoma virus-transformed, non-producer	140	1,910	23,900
	SV40 transformed	5,900	1,820	14,400
Rat	NRK untransformed	7,600	NT	36,900
	Sarcoma virus-transformed, non-producer	60	NT	59,200
Mink	Mink lung untransformed	28,200	NT	64,200
	Sarcoma virus-transformed non-producer	1,500	NT	36,400

The binding assays were performed as in Fig. 1. All proteins were bound to monolayers of log phase cells containing approximately 1×10^6 cells per 60-mm Petri dish. The bindings were performed in binding buffer for 40 min at 37°C . The quantitative differences for the individual ligands used are as follows: mouse EGF, 3 ng of ^{125}I -labelled peptide containing approximately 110,000 c.p.m. and 10 μg of unlabelled material to correct for nonspecific binding; gp70, 6 ng of radiolabelled material containing approximately 68,000 c.p.m. and 10 μg of unlabelled peptide to correct for nonspecific binding; concanavalin A, 10 ng of radiolabelled peptide containing approximately 640,000 c.p.m. and 14.5 mg of alpha methyl-D-mannoside⁴² to correct for nonspecific binding. Of the cell lines tested the SV40-transformed clone (SV-A31-CL6) has consistently given somewhat lower levels of concanavalin A binding compared with both normal and other transformed clones. Whether this is a general property of SV40-transformed clones is not yet clear.

cell lines, it seems that there is one major class of receptors that bind EGF and there is little evidence for cooperative binding or for the existence of a significant fraction of secondary, low-affinity receptors.

Specificity of the cell membrane change

To determine whether the profound alteration in the EGF-binding properties of sarcoma virus-transformed cells is a manifestation of a more generalised membrane alteration, we tested other ligands that bind to cells (Table 3). The major mouse leukaemia virus glycoprotein, gp70, has high-affinity receptors on mouse cell membranes⁴¹. Normal mouse cells in culture can bind gp70, whereas cells that are actively producing type C viruses, either as a result of external infection or as a result of activation of endogenous virogenes, lose the ability to bind the purified viral envelope glycoprotein, because the receptors are occupied by gp70 molecules⁴¹. As shown in Table 3, clone A31 cells have detectable receptors for gp70 whereas cells infected with and producing mouse leukaemia viruses have none. Although sarcoma virus-transformed non-producer cells as well as transformed virus-producing cells do not bind ^{125}I -EGF, only those clones actually producing virus have lost detectable receptors for gp70. SV40-transformation affects neither the binding of gp70 to cell membranes nor the binding of EGF to its specific receptors.

Concanavalin A (con A), binds to cell membranes of

normal and transformed cells⁴². As shown in Table 3, there are only small differences between normal, MSV-transformed, or SV40-transformed cells in the binding of ^{125}I -labelled con A to cell membranes when low concentrations (7 ng ml^{-1}) are used. Insulin receptors have also been reported to show no difference in binding between MSV-transformed and SV40-transformed cells⁴³.

EGF binding after sarcoma virus infection

The loss of detectable EGF binding to MSV- and FeSV-transformed cells suggests that an alteration of EGF receptors is one of the specific effects of infection by some sarcoma viruses at least. However, since the cloned cell lines used in our studies were tested many generations after the initial transformation event, the results could reflect late, secondary effects associated with transformation but not necessarily with the sarcoma virus. To test this possibility, normal mink, rat and cat cells were infected with Kirsten sarcoma or feline sarcoma viruses and EGF binding was assayed as a function of time after infection. An effect on EGF binding was seen as early as 2 d after infection with feline sarcoma virus and 3 d after infection with murine sarcoma virus (Table 4). At this time, the cells were just beginning to show morphological evidence of transformation. By 6 d the effect on EGF receptors was pronounced, and by 2 weeks when most of the cells were clearly transformed, the EGF binding was greatly reduced. Since the

Table 4 Effect of MSV and FSV infection on the binding of EGF to the receptors of various mammalian cells

Cells	Virus	Time (d)	^{125}I -EGF (c.p.m. per 10^6 cells)		
			Control	MSV infected	% of control
MvILu	K-MSV (M28 baboon virus helper)	0	25,800	26,400	102.3
		3	29,400	19,800	67.3
		5	22,800	9,900	43.3
		14	25,500	4,800	18.8
NRK	K-MSV (SSAV virus helper)	0	12,500	14,200	113.6
		3	15,500	7,300	47.1
		6	14,200	4,300	30.3
		14	12,700	700	5.5
Cat embryo (FFc60WF)	GA-FSV (FeLV virus helper)	0	2,400	2,300	95.8
		2	2,800	1,400	50.0
		4	2,400	1,200	50.0
		6	2,500	950	38.0
		14	2,200	320	14.5

At time zero 20% confluent Petri dishes were infected with 1 ml of banded sarcoma virus stock diluted 1:10 with DMEM containing 10% calf serum. The controls were parallel flasks infected in the same manner with helper leukaemia virus free of sarcoma virus. At the indicated time after infection, two dishes each were taken for binding assays as described in the legend to Table 1 using ^{125}I -mouse EGF (3 ng containing 110,000 c.p.m.).

Table 5 Mouse cell virogene expression and oncogenic expression; availability of receptor sites

Cell line	Virus production	gp70 receptor binding	Cell transformation	EGF receptor binding
Mouse embryo diploid	—	+	—	+
BALB/3T3	—	+	—	+
BALB/3T3—MuLV producer	+	—	—	+
BALB/3T3—MSV-transformed, non-producer	—	+	+	—
BALB/3T3—MSV-transformed, MuLV producer	+	—	+	—

mammalian sarcoma viruses are unable to replicate by themselves⁴⁴, sarcoma virus preparations contain mixtures of defective sarcoma viruses and "helper" type C leukaemia viruses. Control cells used in these experiments, therefore, were infected with the helper virus alone (FeLV in the case of the cat cell infection, SSAV⁴⁵ for the rat cell experiment, and the baboon virus M28⁴⁶ for the mink cell infection). None of the non-transforming viruses could be shown to affect EGF binding. From these experiments we conclude that the alteration in EGF binding to MSV- and FeSV-transformed cells represents an early event following infection that can be demonstrated within two to three cell divisions; in fact, this change may serve as an early index of transformation by murine and feline sarcoma viruses.

EGF receptors and gp70 receptors

BALB/3T3 (clone A31) is not morphologically transformed and is not spontaneously producing endogenous type C viruses⁴⁷. It has 5×10^5 – 6×10^5 leukaemia virus gp70 receptors per cell⁴⁸ and 4×10^4 – 5×10^4 EGF receptors per cell (unpublished results). In these properties the clone resembles normal mouse diploid embryo cells (Table 5). After exogenous infection with mouse leukaemia viruses or after activation of endogenous type C viruses the cells no longer bind the viral envelope protein, gp70; they nevertheless continue to bind labelled EGF. Clones of A31 transformed by MSV but not producing virus, on the other hand, retain available receptors for gp70 but no longer bind labelled EGF. Cells that are both transformed by MSV and are producing virus have available receptors for neither gp70 nor for EGF.

EGF as a possible transforming protein

The genes which code for the gp70 receptor as well as those for gp70 itself are endogenous and genetically transmitted in mouse cells. In fact, gp70 has been shown to be a differentiation antigen found on the surface of normal mouse thymocytes^{47–49} and certain other cell types⁵⁰ which are not actively producing type C viruses. Similarly, both the genes for the EGF receptors and for EGF itself must be transmitted as part of the mouse genome. Our results suggest that an alteration in the EGF receptors is a significant early event associated with transformation by murine and feline sarcoma viruses. The decreased levels of EGF binding found in MSV-transformed cells might reflect (1) an indirect effect of the sarcoma gene product on the synthesis, degradation, or location of functional EGF receptors or (2) the production of endogenous EGF or a related substance that binds to the EGF receptors.

One possible model consistent with the data is that the sarcoma genes code for an EGF-related substance and, thus, inhibit binding by added hormone. Sarcoma viruses have arisen by recombination between "helper" type C viruses and sarcoma-specific cellular sequences^{6,9}. Thus, transformation resulting from expression of "sarc" genes need not be a consequence of sarcoma virus infection, but alternatively, may result from the expression of endogenous "sarc" genes (oncogenes). If the sarcoma gene expression is causally related to the alterations in EGF receptors, the model would predict that certain "non-viral" transformants would also show decreased levels of EGF binding. We have

so far examined 15 chemically-transformed clones derived from BALB/3T3 and have found one benzopyrene-transformed A31 clone that has greatly reduced EGF binding, similar to that seen with the MSV transformants. In this chemically-transformed line, it may be that an endogenous factor, perhaps EGF itself, is produced which can alter the EGF receptor and thereby provide a continued endogenous stimulus for cell division.

Various other polypeptide growth stimulatory hormones such as fibroblast growth factor (FGF)^{51,52}, nerve growth factor (NGF)⁵³, insulin⁵⁴ and multiplication stimulation activity (MSA)^{54,56} have been described. These also have some of the properties we might expect of a transforming protein. The specific receptors for each of these other hormones are distinct from those that interact with EGF^{57,58–60} and comparisons of DNA virus- and RNA virus-transformed cells have so far only been made for insulin receptors⁴³ where no differences were seen. The EGF binding data described here lead to the conclusion that SV40 and polyoma, each of which also carries a gene(s) for transforming proteins, exert their action elsewhere, and do not involve the EGF receptor-growth regulatory system.

We thank Mary Ann McDonald and Charlotte Meyer for technical assistance and Dr Charles Sherr for helpful suggestions. This work was supported by the Virus Cancer Program of the National Cancer Institute. S. C. is an American Cancer Society Research Professor.

Partial denaturation mapping of cloned histone DNA from the sea urchin *Psammechinus miliaris*

Rudolf Portmann, Walter Schaffner & Max Birnstiel

Institut für Molekularbiologie II der Universität Zürich, Winterthurerstrasse 266A, 8057 Zürich, Switzerland

A cloned 5.6-kb DNA repeat unit of Psammechinus miliaris containing all five histone coding sequences of known order and polarity has been shown to fall clearly into a low melting and a high melting half by thermal denaturation. The topologies of the DNA sequences thus defined were determined by partial denaturation mapping in the electron microscope to gain further insight into the distribution of spacers and genes within histone DNA.

THE five histone coding sequences of the sea urchin *Psammechinus miliaris* alternate with spacer DNA within a (nominally) 6-kilobase (kb) DNA unit¹ which is tandemly repeated several hundred times^{2,3}. The coding sequences are on the same DNA strand⁴ and are arranged in the order H4, H2B, H3, H2A and H1 (ref. 1). Transcription proceeds in the H4 to H1 direction⁴. In sea urchins, neither the site(s) of initiation of transcription nor the nature of the primary transcript is known, but there is some evidence that HeLa cells contain a high molecular weight nuclear precursor to cytoplasmic histone RNA (M. Melli, G. Spinelli, H. Wyssling and E. Arnold, in preparation).

There has already been extensive restriction mapping¹ and some sequencing (unpublished results) of the histone DNA repeat units of *Psammechinus miliaris*. An alternative approach for the elucidation of the sequence organisation of this DNA is to examine partially denatured DNA molecules in the electron microscope. This will reveal the gross topologies of DNA sequences and will permit the identification of regions of particular interest within the molecule. We have taken this approach and have used for a protein-free spreading technique⁵, the first time that it has been applied to partial denaturation mapping in a quantitative way.

GC-rich genes and AT-rich spacers

Histone mRNA of sea urchin has been found to be rich in GC (50-56%) by base composition analysis^{6,7}. RNA-DNA hybrids from the histone mRNA subfractions I-III and V of *Psammechinus*, now known to represent the individual mRNAs for H4, H2b, a mixture of H3 and H2A and for H1⁸, respectively, all have the high melting temperature of 75-76 °C in 0.1 × SSC^{2,3}, as would be expected from the high GC content of the sea urchin histone mRNA. By contrast, the intervening spacer DNA is rich in AT. This was first inferred from the banding position (1.704 g ml⁻³; ref. 9) of histone DNA in CsCl and was later substantiated by *T_m* measurements on isolated histone DNA¹. Consequently, histone

DNA consists of two major types of DNA—GC-rich histone coding and AT-rich spacer DNA sequences.

There are also some definite predictions on the amounts of GC-rich DNA that can be made. The coding sequences for the five histone polypeptides can be calculated to require about 2.13 kb (Table 1). Sea urchin mRNA H4, however, contains additional, untranslated sequences of about 100 nucleotides¹⁰. If stretches of similar size are also found in the other histone messengers, the coding sequences for all five would be of the order of 2.7 kb, or about half the repeat length, now determined to be 5.59 ± 0.35 kb by electron microscopy (see below).

The melting profile of the histone DNA, reclaimed from the recombinant phage λ b538 redB113 *imm*^{4,34} (Pm histone)-22 (ref. 11) by restriction⁴ is quite simple and has all predicted characteristics (Fig. 1). It falls clearly into early melting and late melting halves. The second major transition has a *T_m* of 74.8 °C (52% GC).

Fig. 1 Melting profile of reclaimed h22 DNA. h22 was isolated from λ h22¹¹ by restriction with *Hind*III and preparative gel electrophoresis as described earlier^{4,20}. The DNA was dialysed exhaustively against 0.1 SSC (▲) or 10 mM NaAc (●), pH 8, and the DNA (10 μ g ml⁻¹) was heated in a Beckman Acta III spectrophotometer. The heating increment was 0.5 °C per min. Bacterial DNAs from *Escherichia coli* and *Micococcus lysodeikticus* melted at 74 °C and 85 °C, respectively, histone mRNA/DNA hybrids at 75 °C (ref. 3).

Restriction of the recombinant DNA yields λ h22 fragments I and II of 9.1 and 1.1 kb. Others clones, with histone DNA inserted in the opposite way, produce fragments of 4.9 and 5.3 kb (unpublished results of W. Schaffner).

Fig. 2 a, Histogram of 37 partially denatured λ h22 molecules. The frequency of DNA denaturation with map units is given at a resolution of 50 base pairs or 0.12 map units. The areas of the black fields can be taken as a measure of the amount of denatured DNA. In the orientation chosen in Fig. 2a the transcription of the histone genes in the sea urchin would be left to right. The 10-kb 'right' arm of the receptor phage extends from map units 75.8–100%. It includes the typical λ blister¹⁶ at 97.2%. The insertion points for the eukaryotic DNA map at 61.5 and 75.8%, respectively, with a histone DNA intervening between them. On average 37% of the inserted h22 was denatured with blisters appearing at 65.0, 67.5, 70.0 and 73.3%. Even the terminal 80 base pairs near the H4 gene, seen as small fork in Fig. 4, can be detected as blister in intact recombinant DNA in some molecules. **b**, Restriction map of λ h22. The recombinant DNA is shown schematically in the orientation which is standard for λ phage. The large black arrows mark the integration points for h22 DNA which are also the cleavage sites for the *Hind*III restriction enzyme. The arrangement and polarity of the histone-coding sequences within the recombinant has been indicated (see text). There are four recognition sequences for the *Eco*RI restriction enzyme in the λ receptor phage, one in h22.

Its thermostability is that anticipated from the base composition of histone DNA and from the T_m of the mRNA–DNA hybrids. The fraction of DNA in this component is consistent with the idea that half the histone DNA is contributed by the coding sequences for the five histone mRNAs, inclusive of untranslated leading and trailing sequences. The other half of DNA melts at 65.6 and 68 °C, respectively, and because of its calculated composition^{12,13} of 34% and 40% GC would not be expected to code for histone mRNA¹. It is taken to represent the AT-rich spacer DNA.

Since the two major melting steps are clearly separated from one another by a pronounced plateau which extends over 4–5 °C, a situation prevails which is ideal for partial denaturation mapping. Conditions can be chosen in which all the AT-rich DNA segments are melted out while leaving the GC-rich regions virtually untouched. The topologies of the DNA segments can then be determined in the electron microscope.

Orientation of the recombinant histone DNA

Partial denaturation mapping in the electron microscope has the disadvantage that it is often impossible to establish the orientation of the gene arrangement from the blister map alone. But 'left' or 'right' of the molecule can be determined if the experiment is performed on uncleaved λ phage DNA into which histone DNA has been inserted in a unique orientation.

The recombinant DNA λ b538 *redB*113 *imm*⁴³⁴ (Pm histone)-22, λ h22 for short, is composed of three elements: the 27-kb left arm, the 10-kb right arm of the receptor phage and the 5.6-kb histone DNA unit intervening between them¹¹. Whenever required, the 5.6-kb histone DNA can be reclaimed from the recombinant DNA by digestion with *Hind*III and fractionation of the three fragments by gel electrophoresis⁴.

The λ -receptor phage contains, in addition to the single *Hind*III site into which the histone DNA was initially inserted¹¹, recognition sequences for a second restriction enzyme, *Eco*RI as indicated in Fig. 2¹⁴. The same enzyme also cleaves histone DNA asymmetrically within the spacer between the H4 and the H2B coding sequence (ref. 1, see Figs 2b and 4b). When the histone DNA recombinant is subjected to *Eco*RI restriction, the products will include two unique DNA fragments which are part histone and part λ DNA. The distances between the *Eco*RI cleavage site within histone DNA and the nearest sites in the λ molecule on either side will clearly depend on the orientation of the histone DNA molecule within the receptor phage. For λ h22, two fragments of 9.1 and 1.1 kb were found by the Southern hybridisation technique (ref. 15; data not shown). For this hybrid phage the orientation given in Fig. 2b applies.

Denaturation mapping requires heating of the DNA in low ionic strength media, to which formaldehyde is added to prevent snapback of the single-stranded DNA regions. For reclaimed histone DNA in 10 mM NaAc, pH 8, the plateau between low and high melting DNA was found at 60–65 °C (Fig. 1). The effects of formaldehyde cannot be gauged accurately because this agent fixes single-strand DNA regions during thermal breathing of the molecules¹⁶. Using the melting profiles as rough guidelines the conditions appropriate for partial denaturation of the histone DNA molecule had to be determined empirically. In the event, recombinant DNA in 10 mM NaAc, 3.5% formaldehyde, pH 8, was reacted at 61 °C for 10 min, the DNA spread with a protein-free technique (ref. 5; see legend to Fig. 3) and photographed in the electron microscope.

All intact molecules were selected which had the well known, characteristic blister in the distal area of the λ right arm^{16,17} (at map position 97.2%, see Fig. 2a) and the molecules were oriented

Fig. 3 Partially denatured h22 DNA. For explanation see text. h22 ($10 \mu\text{g ml}^{-1}$) was heated in 10 mM NaAc, 3.5% formaldehyde, pH 8, to 61 °C for 10 min, and cooled rapidly on ice. After 5 min an equal volume of a mixture containing 60% formamide, 180 mM NaAc, pH 8, and $7.2 \times 10^{-3}\%$ benzylidimethyl-alkylammonium chloride (BAC) was added. 2 μl of the DNA solution was deposited slowly onto the water surface in the centre of a Petri dish (diameter 16 cm) and the spreading of the film monitored by observation of the movement of fine graphite powder placed previously on the water. Carbon-coated 400-mesh copper grids were touched to the surface, the grids washed by floating them on bidistilled water, then stained in uranyl acetate and shadowed with Pt-C. The spreading technique was essentially that of Vollenweider *et al.*⁵ Electron microscopic pictures on Kodak image plates were taken at an instrumental magnification of $\times 8,500$ in a Siemens Elmiskop 101 and the topologies of the DNA segments were determined²⁶ using a map ruler at 1 mm resolution.

Fig. 4a. Histogram of partially denatured h22. The diagram depicts the frequency of denatured DNA with map distance calculated from 118 partially denatured h22 molecules. The orientation of the DNA has been chosen on the basis of experiments described in Fig. 2a and b. On average, 53% of the h22 DNA had been denatured as was required on the basis of the melting profile shown in Fig. 1b. Assignments of mRNA coding, spacer and restriction enzyme sequences to the partial denaturation map. The distribution and the average length of DNA in blisters and double-stranded DNA was calculated from the histogram shown in (a). The length of denatured DNA segments were shortened by a factor of 1.1 to correct for the more extensive stretching of single-stranded DNA. The overall length of the molecule was taken at 5.6 kb (see text). The assignment of the coding sequences was made on the basis of published hybridisation data¹. The known cleavage sites of a selection of restriction enzymes^{1,20} have been indicated in the map. 1 = *Hind*III, 2 = *Eco*RI, 3 = *Hpa*I, 4 = *Hind*II. Transcription of the coding sequences is left to right⁴.

with respect to this region. Thirty-seven partially denatured λ h22 molecules were standardised to a hundred map units and the frequency of occurrence of all blisters along the λ DNA molecules were determined. The diagram in Fig. 2a was thus obtained.

Partial denaturation map of histone DNA

First, reclaimed histone DNA was spread for inspection in the electron microscope⁵ and the lengths of the native molecules determined by comparison with added T7 marker molecules. Thirty-five T7 molecules, taken to represent 37.8 kb (ref. 18), averaged out at $12.64 \pm 0.56 \mu\text{m}$. 235 h22 molecules were measured from the same grids. A length of $1.87 \pm 0.12 \mu\text{m}$ or $5.59 \pm 0.35 \text{ kb}$ was found.

With the aim of achieving denaturation of approximately 50% of the DNA molecule, h22 was heated to 61–62.5 °C in 10 mM NaAc, 3.5% formaldehyde, pH 8, and spread for electron microscopy. Partially denatured histone DNA molecules like that shown in Fig. 3 were obtained. The h22 molecule terminates in a small fork at one end, a larger one at the other. Because of this, the denaturation pattern is clearly asymmetrical and so there was no difficulty in orientating the DNA molecules. The denatured and native lengths of 118 molecules in all were measured and their overall lengths were standardised to 100 map units. The frequency of denatured DNA stretches in these molecules is given as a function of map distance at a resolution of 28 base pairs in Fig. 4a.

Anatomy of the cloned histone DNA

The histogram in Fig. 4a shows that the *Psammechinus miliaris* histone DNA h22 consists of AT- and GC-rich DNA stretches intermingled with one another. A small open fork and a small double-stranded stretch are separated, on the left, from a series of three native segments of similar size. Adjacent to these, further to the right, is a middle-sized blister followed by a relatively large unmelted region which terminates, in most cases, in an open fork structure. Since in the sea urchin the 5.6-kb repeat units are joined together without any intervening DNA¹⁹ and are tandemly arranged many hundred times². The two terminal forks can be imagined to be linked in such a way that on denaturation they would form an intact fifth blister on chromosomal DNA.

Except for the joining points between λ and inserted histone DNA, marked by arrows, the blister map of the integrated and the reclaimed isolated h22 DNA shows striking similarities. The black areas in the histogram of Figs 2a and 4a contributed by denatured DNA are clearly different from one another and if numbered 1–4,

from left to right, can be arranged in the order $2 \leq 3 < 4 < 1$ in both diagrams. The polarity of the histone gene cluster in the λ -receptor phage is known (see above). It can be applied to the isolated h22 molecule on the basis of the distinctive blister pattern for both these kinds of molecules. This has been done in Figs 3c and 4b.

For quantitative considerations it is more convenient to discuss the DNA lengths in base pairs rather than in map distances. For this, we have to take account of the fact that denatured DNA⁵ is stretched out by a factor of 1.1 compared with native DNA and hence that the length would be overestimated in an uncorrected linear diagram. The standardised length in base pairs, calculated from a line dissecting the diagram of Fig. 4a at half height, is given in Fig. 4b. The summation of the lengths of all double stranded DNA segments (Table 1) shows that, on average, 53% of each molecule had been denatured.

The partial denaturation map supports the general model for *Psammechinus* histone DNA in which the five genes coding for the five histone proteins alternate with AT-rich spacer DNA. A similar arrangement has been made visible in the electron microscope for histone DNA from another sea urchin by M. Wu, D. Holmes and N. Davidson (California Institute of Technology) using their novel RNA–DNA hybridisation procedure. An intermingling of spacers and genes had previously been suggested by the results of a combined attack on the histone DNA by restriction and molecular RNA–DNA hybridisation¹. In these experiments, it was possible

Table 1 Number of base pairs in histone and histone mRNA coding sequences

Histones	No. of amino acids in protein	Amino acid coding sequence (bp)	mRNA coding sequence (bp)	GC-rich DNA segments (bp)
H4	102 (refs 21 and 22)	306	400 (ref. 8)	440
H2B	125 (ref. 23)	375	ND	500
H3	135 (ref. 24)	405	ND	470
H2A	128 (ref. 24)	384	ND	530
H1	Heterogeneous approx. 220	660*	ND	680
all five		2.62 kb		2.13 kb

Values for H3, H2A and H1 are those for mammals

*There is some circumstantial evidence²⁵ that the H1 of the sea urchin may be smaller than that of mammals

to subdivide the histone DNA repeat unit into five segments of similar size, each of which hybridised to just one histone mRNA but contained a considerably greater amount of DNA than would be required to code for a single histone protein.

In that work, the restriction enzymes *HindIII*, *HindII*, *EcoRI* and *HpaI* were shown to cleave histone DNA between the coding sequences, that is in spacer DNA^{1,20}. Since these cleavage sites have all been mapped by gel electrophoresis of the restriction fragments, their positions can now be found on our partial denaturation map (Fig. 4b). The cleavage sites fall into the blister regions or just within the GC-rich DNA segment near the interphase between melted and unmelted DNA with the exception of one *HindII* site which lies near amino acid 105 of the H2B coding sequence (unpublished results). It has been found that other restriction enzymes cut preferentially in coding sequences, while leaving spacer DNA virtually intact²⁰.

The sequence of 97 nucleotides from the 'left' end of h22 has been determined (unpublished results of H. O. Smith and M. L. Birnstiel). The first 60 of these averaged at a GC content of 34%, while the subsequent DNA stretch contained 50% GC. This demonstrates that the small fork detected in our partial denaturation map near the H4 coding sequence did not arise simply due to breathing of the DNA ends, but reflects the compositional bias of this terminal DNA segment. Here too, there is good accordance between the biochemical and the structural data. Throughout the work we have also noted that the protein-free spreading technique⁵ has provided a reliable means for partial denaturation mapping at high resolution.

Perhaps the most striking correlation that can be drawn is that between the molecular weight of histone proteins and the size of the GC-rich DNA segments delimited on either side by the DNA blisters. The H4 proteins of sea urchins is known to be made up from 102 amino acids^{21,22} and its mRNA to contain some 400 bases^{6,7}. In our map, the DNA assigned to this mRNA is 440 base pairs (Table 1). The largest histone, H1, contains some 220 amino acids²³ and hence some 660 base pairs would be required for its

coding. In keeping with this, the largest double-stranded region is found at the location predicted for the H1 gene. Here, as well as for the middle group of the histone-coding sequences H2A, H2B and H3 there is an excess of base pairs which may code for the leading and trailing sequences of these histone mRNAs. The base sequence arrangement of some of these regions, of spacers and genes will be reported shortly.

We thank H. Datwyler, Edith Bohl and Arlette Binkert for assistance. H. O. Smith and S. Clarkson kindly provided λ h22 and h22 for some of the experiments. We thank Professors T. Koller and R. Wyler, Zurich, for electron microscopy facilities. The work was supported in part by a grant from the Schweiz Nationalfonds and by the State of Zürich.

Overlapping genes in bacteriophage ϕ X174

B. G. Barrell, G. M. Air & C. A. Hutchison III*

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

Bacteriophage ϕ X174 genes D and E are translated from the same DNA sequence but in different reading frames.

BACTERIOPHAGE ϕ X174 contains a single strand of DNA approximately 5,400 nucleotides in length, which has been shown to be of the same sense as the mRNA and to code for nine cistron products. As shown in Table 1, there is an apparent discrepancy between the length of the DNA in the genome and the amount required to code separately for the proteins; significantly more DNA would be needed to code for proteins of the accepted molecular weights than is available. An almost complete sequence of ϕ X DNA has been obtained in this laboratory using the "plus and minus" technique of Sanger and Coulson¹, confirming that the length of the DNA is not more than 5,400 nucleotides (G. M. A., B. G. B., N. L. Brown, A. R. Coulson, J. C. Fiddes, C. A. H., F. Sanger, P. M. Slocombe and M. Smith, in preparation). At the same time, a study of the amino acid sequences of the major ϕ X coded proteins has enabled the boundaries of genes D, J, F, G and H to be located on the restriction map of ϕ X DNA (Fig. 1). Table 1 shows that the molecular weights of the F, G, J and H proteins have been found to be close to correct, while the

D protein molecular weight is somewhat larger than the sodium dodecyl sulphate (SDS) gel estimate. It has not yet been possible to determine directly the boundaries of genes A, B and C in the remaining region between gene H and gene D. The order of genes D to H is in agreement with the genetic map of ϕ X reported by Benbow *et al.*⁴ except that they located gene E between D and J. Here we report the DNA sequence from the promoter preceding gene D through to gene J. We find that gene E amber mutations lie within the DNA sequence which codes for the gene D protein, and interpret this to mean that genes D and E overlap on the DNA sequence. Sequences of gene E amber mutations show that D and E are translated in two reading frames from a common DNA sequence.

It should be emphasised that genes D and E seem perfectly independent by normal genetic criteria. The D protein is produced in large amounts in the infected cell. It is necessary for the production of viral single-stranded DNA, but its precise role in this process is unclear and there is no evidence that it is directly involved in DNA synthesis^{5,6}. Gene E is responsible for lysis of the host cell. All nonsense mutants in gene E characterised so far produce completely functional full size gene D protein. In fact, the protein chemistry of the gene D protein which is reported in this paper has been carried out using material produced by an amber mutant in gene E (*am3*). Similarly, normal gene E function has been observed in the gene D nonsense mutants.

Total		>6,078	5,374§	
Length of ϕ X174 DNA		~5,370		

*There is considerable variation in reported molecular weight estimates of ϕ X174 coded proteins. The values given are those most frequently recorded, or recently reinvestigated^{4,22,28–33}.

†Protein molecular weights are calculated from the number of nucleotides using the formula:

$$\text{Protein molecular weight} = \text{No. of nucleotides} / (3 \times 0.00915)$$

‡These values are calculated from the amino acid sequences (Freymeyer *et al.*, in preparation; ref. 35 and this paper).

§This figure includes the 160 nucleotides of the intercistronic regions so far determined.

Nucleotide sequence analysis of the gene D region

The cleavage sites of ten restriction enzymes of different specificities have been mapped on ϕ X174 RF I (double stranded) DNA. The cleavage sites of these enzymes in the gene D region are shown in Fig. 2.

Using the restriction fragments shown in Fig. 2 as primers with either the (+) or (–) strands of ϕ X DNA as a template, sequences of approximately 100 residues on either side of all the restriction enzyme sites in this region were determined using the plus and minus technique of Sanger and Coulson¹. Figure 3 shows a good example of this method using fragment *Taq* 4 as a primer on ϕ X (–) strand DNA cleaved with *Mbo*II. A long and a short fractionation of the same reactions is shown, from which an almost unambiguous sequence of at least 126 residues can be deduced, starting 14 residues from the *Mbo*II 1/7 site.

Fig. 1 A map of ϕ X174 DNA. The boundaries of genes D, E, J, F, G and H are shown aligned with the restriction maps of *Hae*III (fragments designated Z) and *Hind*II (fragments designated R)^{2,3}. The precise location of genes A, A', B and C have not yet been determined.

In this way a large number of overlapping sequences from each restriction site and from both strands were obtained which was more than enough to deduce the entire sequence of the gene D region. Although the method is very reliable these overlapping sequences overcame some problems encountered with the plus and minus technique. One disadvantage is that the first 15 residues from the restriction site are not normally seen on the acrylamide gels. This is probably due to the instability of short products on the template which are subsequently degraded by the exonuclease activity of the DNA polymerase present during the restriction enzyme digest of the plus and minus reactions. Another problem encountered is unequal "jump sizes" on the gel between products differing by one residue in length. These occurred in specific regions of the sequence, probably due to local secondary structure at the end of products which were not completely denatured during gel electrophoresis. Electrophoresis at high current (high temperature) gives much improved separation. This problem could also be overcome by priming in the same region from an adjacent restriction site but on the complementary strand. An early difficulty in deducing accurately the number of residues in a run of a particular nucleotide has been overcome by including alongside the plus and minus reactions on the gel a digest of the initial incorporation. This gives a graticule of every possible chain length of the newly synthesised DNA from the restriction enzyme site.

In some cases other techniques such as limited exonuclease digestion of rCTP or rGTP substitution products^{9,10} and depurination of nick-translated restriction enzyme fragments¹¹ have been used to confirm the sequences deduced from the plus and minus system where they were in any doubt. The DNA sequence is shown in Fig. 4.

Amino acid sequence analysis of the D protein

A further confirmation of the DNA sequence was provided by amino acid sequence analysis of the gene D protein. Figure 5 shows the sequences of the protein and of the peptides derived by trypsin, chymotrypsin, thermolysin and cyanogen bromide digestion. The DNA sequence has been used for overlapping several peptides, and amino acids 58, 59, 93 and 123 were not identified in the protein work. The sequence of the first eight amino acids of this protein has been reported by Farber⁶ but it should be noted that our sequence differs by a serine replacing arginine at residue 7. The calculated molecular weight of the protein is 16,811 which is somewhat higher than the estimates from SDS gel electrophoresis of 14,500 daltons

Fig. 2 Restriction map of the gene *D* region. The cleavage sites are shown of *Hind*II, *Hae*III (refs 2 and 3), *Hap*II (ref. 7), *Hha*I, *Hae*II, *Hinf*, *Alu*I (ref. 3), *Taq*I (S. Sato, C. A. H., and J. I. Harris, in preparation), *Mbo*II (N. L. Brown, C. A. H., and M. Smith, in preparation)

(Table 1). In 8 M urea-SDS gels the molecular weight estimate is more accurate at ~16,000 (G. M. A., unpublished).

Location of the promoter and genes *D* and *J*

The amino acid sequence analysis of the gene *D* product unequivocally defines the boundaries of gene *D* on the DNA sequence since termination codons are found in phase before the initiation codon and after the C-terminal amino acid codon. This rules out the possibility of a longer precursor to the gene *D* protein. The gene *D* initiation codon lies within the *Hind*II 6b-*Hae*III 3 region reported by Chen *et al.*¹² to contain an RNA polymerase binding site. Smith and Sinshemer¹³ have identified the *in vitro* mRNA start from this region as ppp(C) G-A-U-G-C. We find that this sequence occurs 30 residues to the left of the initiation codon of gene *D* (Fig. 4).

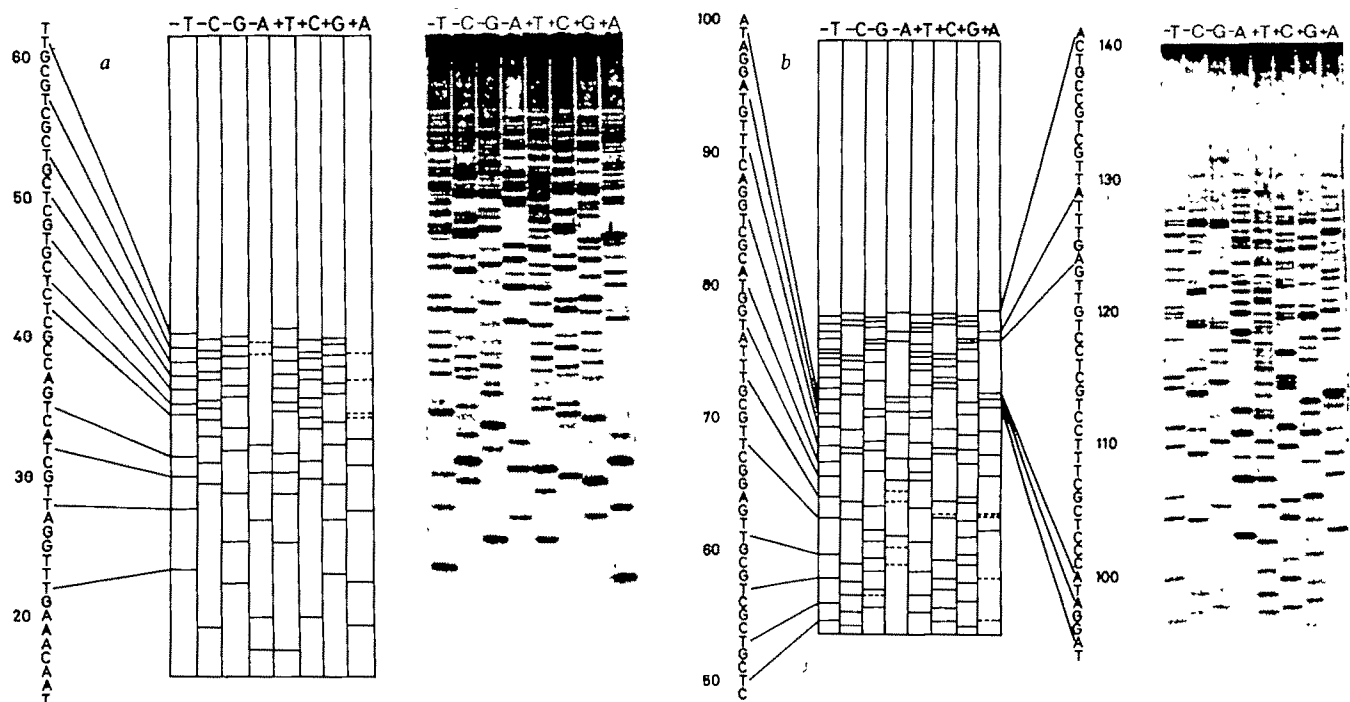

The termination codon of gene *D* overlaps by one nucleotide the initiation codon of gene *J* in the sequence T-A-A-T-G. Overlapping initiation and termination codons have also been

observed in *E. coli* tryptophan mRNA¹⁴. In this case the sequence was shown to be U-G-A-U-G.

Genetic mapping experiments of Benbow *et al.*⁴ suggested the existence of a gene *J* in this region coding for the smallest structural component of the virion. Alignment of the DNA sequence with the amino acid sequence of a small basic protein isolated from the virion (D. Freymeyer, P. R. Shank, T. Vanaman, C. A. H. and M. H. Edgell, in preparation) clearly demonstrates that it is coded by the gene immediately following *D*. We suggest that gene *J* be explicitly defined as the gene coding for this protein since marker rescue experiments show that the mutation (*am6*) which had genetically defined *J* (ref. 4) is located in *Hae*III fragment 7 (ref. 15) which ends 179 nucleotides before the initiation codon of *J* as defined here.

The complete nucleotide sequence of gene *J* has now been determined and has been shown to extend from the end of gene *D* to within approximately 35 nucleotides of the initiation codon of gene *F* (B. G. B., unpublished). This establishes the

Fig. 3 a, An autoradiograph of a plus and minus¹ sequencing gel using fragment *Taq*4 as a primer on ϕ X (—) strand template. The products were cleaved with *Mbo*II. A diagram showing the interpretation of the sequence is shown alongside. Electrophoresis was continued until the bromphenol blue marker reached the bottom of the gel. b, The same reaction as in a but fractionated for a longer time, such that the xylene cyanol marker migrated near to the bottom of the gel.

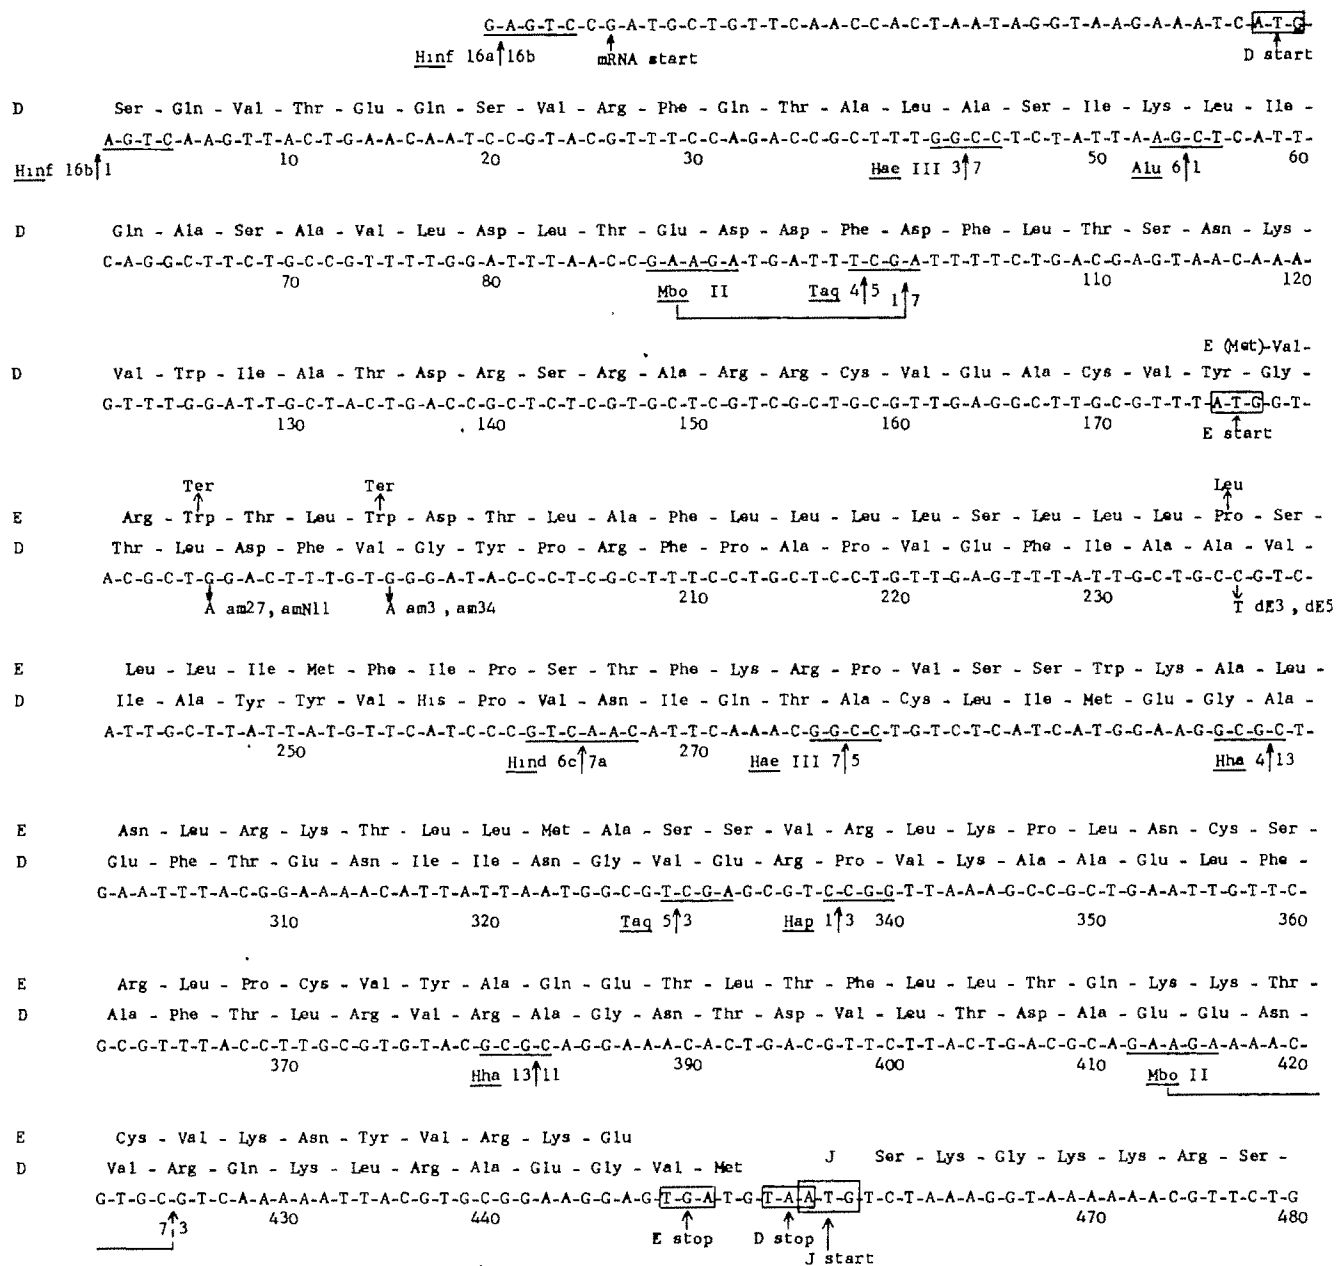

Fig 4. The nucleotide sequence of the gene *D* region. The amino acid sequences of the *D* protein (see Fig. 5) and the *J* protein are aligned with the DNA sequence. The amino acid sequence of the gene *E* product predicted from the DNA sequence is also shown.

order of genes *D*, *J* and *F* in this region, but gene *E* which mapped genetically immediately following gene *D* (ref. 4) is not accounted for.

Location of gene *E* mutants within gene *D*

It is possible to rescue genetic markers from restriction fragments¹⁶ and thus to establish the location of genetically defined sites on the physical map of ϕ X174. This technique has been applied to locate gene *E*. The double-stranded RF DNA of wild-type ϕ X174 was cut with restriction endonucleases and the resulting fragments were purified by gel electrophoresis. Fragments were denatured and annealed to the viral single-stranded DNA bearing a gene *E* mutation.

Spheroplasts of *E. coli* were transfected with the resulting complexes and the progeny phage were selectively assayed for wild-type plaque-forming particles. Wild-type marker can only be rescued from fragments which span the site of the mutation. Several gene *E* mutants were tested in this way, including *am* nonsense mutants. All were rescued by the wild-type *Hae*III fragment Z7 (Table 2). Weisbeek *et al.*¹⁵ have

also mapped one of these mutants (*am3*) and the mutant (*am6*) (probably a gene *E* mutant) in fragment Z7. Surprisingly, inspection of the nucleotide and amino acid sequence data showed that this fragment is completely contained within gene *D* (Figs 2 and 4). Since gene *E* *am* mutants make a full length *D* protein, these gene *E* nonsense codons cannot be in phase with the translation of gene *D*.

Nucleotide sequence of gene *E* mutants

Sequences within *Hae*III fragment Z7 have been determined for several ϕ X174 strains bearing mutations in gene *E*. Figure 6 compares a gel which displays the sequence synthesised on a viral strand template containing *am3* (gene *E*) with a gel showing the corresponding wild-type sequence. The mutation clearly produces a C→T change in the synthesised minus strand which corresponds to a G→A transition at position 195 in the viral (plus) strand sequence (Fig. 4). Thus the mutation results in the minus strand sequence 5'-C-T-A-3' which corresponds to the amber codon 5'-T-A-G-3' on the viral strand. The phase of this nonsense codon is displaced one nucleotide to the right

Fig. 5 Amino acid sequence analysis of the D protein. Sequences of ϕ X174 D protein and peptides derived by tryptic, chymotryptic, thermolytic and CNBr digestion. Solid bars indicate sites of cleavage; the broken bar shows partial cleavage. The residues shown were obtained by automatic (residues 1-17) or manual sequencing. Residues in parentheses were present in the amino acid composition but not identified in the sequencing work. Blanks indicate that the peptide was not sufficiently purified for a reliable amino acid analysis. The protein was isolated from 50 g of frozen ϕ X174-infected *E. coli* C (grown at the Microbiological Research Establishment, Porton Down). Cells were thawed with 50 ml buffer A (20 mM Tris, 10 mM $MgCl_2$, 1 mM mercaptoethanol, 1 mM EDTA pH 8.0), sonicated, and the cell debris centrifuged off, extracted with buffer A and 1 M NaCl, and centrifuged again. The supernatants were dialysed against buffer A at 4 °C, centrifuged again, and the supernatant loaded on a column (3 \times 20 cm) of Whatman DE-52 equilibrated with buffer A at 4 °C. After the unadsorbed proteins had been washed through a linear gradient was started (600 ml each A and A+0.6 M KCl) the D protein eluted about half way through the gradient as monitored by 15% acrylamide gel electrophoresis in 0.1% SDS.

Fractions containing the D protein were combined and 18.7 g $(NH_4)_2SO_4$ added per 100 ml at 4 °C. The resulting precipitate was centrifuged down, resuspended in buffer A, dialysed against buffer A and the suspension centrifuged again. The supernatant contained the D protein sufficiently pure for amino acid sequence analysis. It was dialysed extensively against water and freeze dried.

The amino acid sequencing was by the standard procedures as described previously^{34,35}. The amounts of *S*-carboxymethylated protein used were 2 mg for N-terminal automatic sequencing in the Beckman sequencer, 5 mg for succinylation and tryptic digestion, 2 mg for chymotryptic digestion, 15 mg for CNBr cleavage, and 5 mg for thermolytic digestion. Purification of the insoluble and the neutral thermolytic peptides was not attempted.

Table 2 Rescue of gene *E* mutants by restriction fragments from gene *D*

Gene <i>E</i> mutant	<i>Hae</i> III fragments			<i>Hha</i> I fragments		
	Z3	Z7	Z5	H8(ab)	H4	H13
<i>am3</i>	1.2×10^3	2×10^4	8×10^3	5×10^3	2×10^4	4×10^3
<i>am27</i>	1×10^3	$> 2 \times 10^4$	2×10^3	—	—	—
<i>am34</i>	6×10^1	$> 2 \times 10^4$	6×10^1	6×10^1	2×10^3	2×10^1

<i>dE3</i>	8×10^1	$> 2 \times 10^4$	6×10^1	4×10^1	1×10^4	4×10^1
<i>dE5</i>	1×10^1	2×10^3	$< 10^1$	$< 10^1$	1.2×10^3	$< 10^1$
S13 <i>amEn15</i>	2×10^3	4×10^3	2×10^3	—	—	—

Restriction fragments of wild-type RF DNA were purified by gel electrophoresis. Fragments were denatured, annealed to viral strand from each of the gene *E* mutants listed, and used to infect spheroplasts of *E. coli* as previously reported¹⁶. Wild-type plaque-forming phage were selectively assayed on *E. coli* C (*su*⁻). The number of wild-type phage per ml following chloroform lysis of the spheroplasts is tabulated, and positive results are underlined. In the experiment shown here only fragments from the gene *D* region were assayed. In another experiment (data not shown) all of the *Hae*III fragments and all of the *Hha*I fragments were assayed for the *am3* site and wild-type markers were only recovered from fragments Z7 and H4. The *am* mutants were assayed on *E. coli* HF4714. The *dE* mutants (see text) were assayed on MacConkey agar (Difco) plates. The phage sample was overlaid in a mixture of 2.5 ml of soft agar, 0.25 ml of 5 mg ml⁻¹ egg white lysozyme, 10 μ l of 1 M CaCl₂, and 0.3 ml of an overnight culture of *E. coli* C (*su*⁻). Plates were incubated at 37 °C.

of that used for translation of gene *D*. In this phase a tryptophan codon (T-G-G) is changed to *am* (T-A-G). The mutation does not produce a change in the D product since one valine codon (G-T-G) is changed to another (G-T-A). Similar analysis of an (*am3*) revertant showed that the wild-type sequence was present at position 195.

An independently isolated gene *E* mutant, *am34*, was shown to contain the same altered nucleotide sequence as *am3* (Fig. 4, data not shown). Two other independently isolated gene *E* amber mutants have also been sequenced (*am27* and *amN11*). Both result in G→A transitions on the viral strand at position 186 (Fig. 4, data not shown). This results again in a T-G-G→T-A-G change which produces an amber codon which is in phase with that found in *am3* and *am34*, and displaced one nucleotide to the right of the D translation phase. Again, no coding change is produced in the phase used for D translation (C-T-G→C-T-A, both coding for leucine). The sequence alterations produced by amber mutations at both these sites have been confirmed by pyrimidine tract analysis of the minus strand of *Hae*III fragment Z7. The G→A change reported here for *am* mutations induced by nitrous acid treatment of phage (plus strand) has been predicted by previous studies on the mechanism of nitrous acid mutagenesis^{17,18}.

One observation which seems inconsistent with the results presented here concerns the characterisation of a population of ϕ X174 deletion mutants¹⁹. These deletions were originally interpreted to be located in gene *E* and presumed to be defective only in lysis function. This is inconsistent with our results which predict that any gene *E* deletion would also have a defect in gene *D*. Further analysis of the ϕ X174 deletion population (R. L. Sinsheimer, personal communication) has shown, however, that it must contain deletions from all parts of the genome. We have also investigated this deletion population and obtained evidence that the population does not contain any particles whose only genetic defect is a gene *E* deletion. We observed that all gene *E* *am* mutants tested were able to form plaques efficiently on *su*⁻ hosts when plated on special medium containing bile salts and egg white lysozyme (see legend to Table 2). If simple gene *E* deletions exist it should be possible to clone them on such plates. In fact, about 1–2% of the particles in the deletion population do form plaques on these special plates but not on normal plates on *su*⁻ or *su*⁺ hosts. However, all 20 isolates tested reverted with frequencies reasonable for simple point mutations. Two of these isolates (*dE3* and *dE5*) were mapped by marker rescue on to Z7 and sequenced. Both isolates contain the same missense mutation which produces a predicted Pro → Leu (C-C-G → C-T-G) change in the gene *E* translation phase as defined by sequenced gene *E* amber mutations (position 237, Fig. 4). This would again produce an unchanged D protein since one alanine codon (G-C-C) is changed to another (G-C-T).

Extent of the gene *E* coding region

The gene *E* amber mutations are suppressible in *su*⁺ hosts indicating that gene *E* is being translated at those locations. It is therefore possible to determine the boundaries of the gene *E* coding region by looking for termination codons in the same phase as the amber codons. The termination codon at position 449–451 (Fig. 4) defines the 3' terminus of gene *E* protein as it is the first available termination codon in this phase after the amber mutations. Initiation of the gene *E* protein must occur between the termination codon at position 107–109 and the amber mutations. There are two possible initiation codons in this region, a G-T-G at position 146–148 and an A-T-G at position 176–178. Of these the A-T-G is the only initiation codon preceded by a sequence complementary to the 3' sequence of 16S rRNA that has been implicated in the initiation of protein synthesis^{20,21}. Figure 7 shows a comparison of the predicted gene *E* initiation site with other initiation regions found in ϕ X174. Starting at the A-T-G codon at residues 176–178 a polypeptide of 91 amino acids would be synthesised. We have been unable to identify clearly either the E protein or the *am3* fragment *in vivo* or *in vitro*, so amino acid sequence analysis has not been possible. However, the calculated molecular weight of the E protein is in good agreement with the identification of an *E* gene product with a molecular weight of 10,000 by Burgess and Denhardt²², although other estimates have varied (see Table 1).

Evolution of overlapping genes

The mechanism by which the gene *E* product acts to induce lysis of the infected cell is not clearly understood. There is no

Fig. 6 Sequence of the *am3* mutation site. *Hae*III fragment 5 was used as a primer with either wild-type or *am3* ϕ X (+) strand as a template. Only a portion of the autoradiograph of the minus system is shown in both cases with the sequences of the (–) strand deduced. The viral strand sequence is therefore:

wt 5'-G-T-G-G-G-A-T-A-3'
am3 5'-G-T-A-G-G-A-T-A-3'

Fig. 7 Comparison of the predicted gene *E* initiation site with other known ϕ X174 initiation sites. The boxed areas indicate sequences complementary to the 3' end of 16S rRNA. Dashed boxes show further complementarity if some nucleotides are looped out or mismatched. Known N-terminal amino acid sequences are also shown.

evidence that it functions as a lysozyme. Bile salts in the presence of egg white lysozyme are able to induce lysis of cells infected with mutants deficient in gene *E* function, although lysozyme alone is not sufficient. This suggests that the gene *E* protein may act on the cell membrane. The predicted amino acid sequence of the *E* protein (Fig. 4) is very hydrophobic in the N-terminal region, in particular in the sequence Leu¹¹-Leu¹²-Leu¹³-Leu¹⁴-Ser¹⁵-Leu¹⁶-Leu¹⁷-Pro¹⁸-Ser¹⁹. A large percentage of hydrophobic amino acids including tracts of leucine residues have been observed at the N terminus of precursors to several pancreatic secretory proteins²³ and in the N-terminal region of the light chain IgG precursor²⁴. These N-terminal regions have been proposed to function in the transfer of the proteins across the microsomal membrane. The similarity between these sequences and the N-terminal region of the gene *E*-protein is consistent with a membrane-related activity.

An analysis of possible secondary structure in the *E* protein using the rules of Chou and Fasman²⁵ predicts that the N-terminal hydrophobic region could consist of an α -helix terminating before the proline at residue 21. The missense mutations dE3 and dE5 cause a Pro to Leu change at residue 21. This mutation, which causes a loss of lysis function, could affect the secondary structure of the *E* protein by preventing α -helix termination at this point.

It is interesting to speculate on the evolution of overlapping genes *D* and *E*. It is possible that the size of the ϕ X174 genome is limited by packaging or other unknown constraints. If so, the genes required could only be fitted in either by overlapping or by reading from both strands of the DNA. The gene *D* codons contain a high proportion (40%) of T residues in the third position, as is observed in other ϕ X174 genes^{26,27}. This suggests the possibility that gene *D* arose first and that ancestors of ϕ X174 could survive without a specific lysis gene in their natural environment. It is clear that if some mutational event led to initiation of protein synthesis in a phase one nucleotide to the right of the *D* reading phase the resulting codons would have a high proportion of T residues at the second position. Such codons specify hydrophobic amino acids and it seems plausible that a polypeptide could be produced which would interact with the host cell membrane. This could provide a basis for natural selection leading to an efficient lysis gene. It is worth noting that a gene *E* amber mutant in the closely related phage S13 is rescued by fragment Z7 from *wt* ϕ X174 (Table 2).

It seems likely that translation of the gene *D* protein, which is made in large amounts, would obstruct binding of ribosomes at the *E* initiation site. This might be a convenient control if the *E* protein is only required in small amounts. On the other hand, some control may be required to facilitate initiation of the *E* protein, for example, mRNA processing. Initiation of the gene *J* protein poses a similar problem, since the sequence involved in gene *J* ribosome binding is being translated in both *D* and *E* phases.

The fact that genes *D* and *E* overlap alleviates to some extent the problem of fitting the known ϕ X genes into the available DNA (Table 1). However, it is clear that if the molecular weight estimates of the A, B and C proteins are correct, they cannot be separately coded in the region between genes *H* and *D*. Thus, in spite of the severe constraints imposed on the amino acid sequence by translation in two phases, it seems possible that other examples of overlapping genes may be found.

We thank R. Kamen, N. L. Brown and S. Sato for gifts of enzymes used in this study and R. L. Sinsheimer for supplying the deletion stock. C. A. H. was supported by a grant from the US Public Health Service.

letters to nature

Determination of the time of the shell ejection in nova outbursts

THE light curve of novae is characterised by a sharp rise in brightness, followed by a decrease in light intensity at an ever slowing rate (see Fig. 1). The optical spectrum of novae near maximum consists of emission and absorption line systems superimposed on a continuum. One of the main features of the evolution of novae spectra is the fading of the continuum relative to the emission lines. In late stages, all novae develop the 'nebular' spectrum, consisting almost exclusively of emission lines with no continuum or with a very weak one (see ref. 1). The analysis of the light curve of a nova can reveal the time of ejection of its main shell. In four galactic novae this time was found to vary between 19 and 40 d before maximum.

Table 1 Two characteristic times of four galactic novae: t_L is the time after maximum light at which the spectrum begins to be dominated by emission lines. T is the time before maximum light of the ejection of the main shell.

Nova	t_L (d)	T (d)
CP Lac	15	19
DI Lac	55	20
Nova Cyg 1975	35	35
Nova Serpentis 1970	95	40

Let $\rho = E_l/E_c$, where E_l and E_c are the energies emitted in the lines and in the continuum. For most novae there is a characteristic time t_L such that for $t > t_L$, $\rho > 1$. From data given in the literature it is very difficult to deduce the value of t_L for novae observed in the past. In four novae, however, whose spectra were recorded at the Wise Observatory in the past 2 yr (Novae Sag 1974, Per 1974, Scuti 1975 and Cyg 1975) it was found to vary considerably. Inspection by eye of spectrograms of Nova Cyg 1975 leads to an estimate of $t_L \sim 30$ d, after maximum brightness.

By the definition of t_L , the light curve of a nova at $t > t_L$ describes mainly the evolution of the intensity of the emission lines of the nova shell. If the permitted emission lines of novae, in particular those of hydrogen, are produced by ionisation and recombination, the time scale for intensity variations is the recombination time $\tau \approx (N_e \alpha)^{-1}$. Here N_e is the electron density and α is the recombination coefficient on all levels of hydrogen. At an electron temperature $T_e = 10^4$ K, $\alpha \approx 4 \times 10^{-13}$ cm³ s⁻¹ (ref. 2) and for $N_e < 3 \times 10^7$ cm⁻³ $\tau > 1$ d. An envelope with a density of 3×10^{14} cm⁻³ ejected at a velocity of 500 km s⁻¹ will reach this density in ~ 50 d. Many galactic novae have a 'transition' period in their light curve, during which rapid oscillations with a time scale of a few hours occur¹. If these oscillations are in the photospheric radiation they must be therefore at times $t < t_L$. There are on the other hand some novae whose light curves are smooth, showing no significant oscillations. It is suggestive to conjecture that in these novae t_L is small. Nova Cyg 1975 is a case in point as the small value of $t_L \sim 30$ d and the light curve in Fig. 1 indicate.

Fig. 1 Smoothed light curves of three novae. The curves of CP Lac (middle) and DI Lac (bottom) are from ref. 1. The curve of Nova Cyg 1975 (top) was constructed by Dr I. Kupo from data published in IAU circulars in 1975 and 1976. The magnitude units are on a relative scale.

The intensity of a recombination line is given by

$$I = \alpha_{eff} V N_e^2$$

where α_{eff} is the effective recombination coefficient for the emission of the line and V is the emitting volume². The intensity of a forbidden line at a given ionisation and temperature is also proportional to $V N_e^2$. For an expanding ionised hydrogen shell of a given mass, $N_e V = M$ is the mass of the shell in atomic units. Thus

$$I = \alpha_{eff} M N_e$$

For a thin expanding shell of invariant thickness

$$N_e(t) = N_e(0) [r_0 / (r_0 + vt)]^2$$

where $N_e(0)$ and r_0 are the density and the radius of the shell at $t = 0$ and v is the expansion velocity. Therefore

$$\frac{I(t_1)}{I(t)} = \left[\frac{r_0 + vt}{r_0 + vt_1} \right]^2$$

where t_1 is some reference time.

Let the zero of time be the moment of maximum light in the photometric V band, and let T be the time difference between the ejection of the main shell and maximum light. We assume that the acceleration time of the shell is $\ll T$. The ejection time is thus defined more strictly as the time at which most of the main shell acquires its final expansion velocity v . If the assumption is not

Fig. 2 The observed function $P(t) = [F(0)/F(t)]^{1/2}$ against t for three novae (in same order as in Fig. 1); $F(t)$ is proportional to the observed flux at the time t .

valid, T will be a lower limit to the time difference between ejection and maximum light. We therefore have

$$r_0 \simeq vT$$

At $t > t_L$ the flux F of the radiation of the nova in the V band is mainly the flux in the emission lines of the shell therefore for $t \geq t_1 \geq t_L$

$$\left[\frac{F(t_1)}{F(t)} \right]^{1/2} = \frac{1+t/T}{1+t_1/T} \quad (1)$$

For all $t > 0$ we define

$$P(t) = [F(0)/F(t)]^{1/2} \quad (2)$$

At $t \geq t_1 \geq t_L$ equations (1) and (2) give

$$P(t) = \alpha \times \beta$$

where

$$\alpha = \frac{[F(0)/F(t_1)]^{1/2}}{T+t_1}; \quad \beta = \frac{[F(0)/F(t_1)]^{1/2}}{1+t_1/T} \quad (3)$$

A plot of $P(t)$ against t should become a straight line at $t > t_L$. The parameters of the line give the time of the ejection before maximum light

$$T = \beta/\alpha$$

Figure 2 is a plot of $P(t)$ against t for the novae CP Lac, DI Lac and Nova Cyg 1975. These novae have no transition periods in their light curves, as shown in Fig. 1.

The curves in Fig. 2 do have linear sections and the parameters derived from them are summarised in Table 1. The parameters for Nova Serpentis 1970 are obtained from a similar analysis of the light curve of this nova, given by Hutchings³. The value of T for this nova is much less certain because of the small extension of the light curve beyond t_L .

The reality of the theory put forward here and of the results obtained from it is somewhat confirmed by the shape of the curves in Fig. 2 which follows the expected one. In particular it justifies empirically the assumption of invariant thickness of the expanding shell. An homologous expansion of a thin shell, for example, requires a change in the definition of the function $P(t)$ in expression (2) to $[F(t)/F(t)]^{1/2}$. With such a definition, the fit

of $P(t)$ to a linear expression in t is worse than the one obtained here. This is indicated by a smaller correlation coefficient for the fit for the four novae and by the systematic deviation of the distribution of the points from a straight line. Physically this assumption is justified because the velocity dispersion within gaseous shells of novae is probably much smaller than the expansion velocity. At times when the increase in the thickness of the shell is still small relative to the initial thickness, the thickness of the shell is to a first approximation invariant. An additional test can be performed by deriving the value of T directly from the value of α or from the value of β . Using expressions (3) we indeed obtain consistent values of T from both expressions. This is not a trivial result as α and β are two independent observational parameters.

An obvious improvement of the method suggested here is the recording of the intensity of a specific recombination line, for example H_β , with narrow band photometry, throughout the nova episode. Data points on such a light curve should be significant for this analysis even at $t < t_L$. They are also unaffected by the radiation in forbidden lines which is much more temperature dependent.

I am grateful to Dr I. Kupo for providing me with the light curve of Nova Cyg 1975.

Radioactivity in the galactic plane

We report here what may be the first detection by a nuclear γ -ray transition of a large concentration of interstellar radioactivity. Such a concentration of radioactivity would be expected if heavy nuclei are synthesised explosively in supernovae. We do not have sufficiently conclusive counting statistics to make an incontestable claim, but the phenomenon we have observed in the background of our measurements is tantalisingly near to theoretical expectations.

The observation was made during balloon-altitude measurements of γ -ray energy spectra in the 0.02–12.27 MeV energy band from galactic and extragalactic sources. These measurements were conducted from Rio Cuarto, Argentina, during April 1–2, 1974. The measurements and the actively-collimated scintillation counter we used have been described elsewhere^{1,2}. In each measurement, a given source was observed for many time segments (each averaging 10 min) that we alternated with equal duration, equal zenith-angle measurements of the background. A galactic co-ordinates plot of the relevant background pointing directions is shown in Fig. 1 of ref. 1; the background series starts with segment³ 1 and ends with background segment 22. The tenth, eleventh and twelfth of these sequential background observations (hereafter labelled B10, B11, and B12) were made in directions towards the plane of the Galaxy—B10 has the lowest average galactic latitude—while the other backgrounds were measured at higher galactic latitudes. B10, B11 and B12 displayed enhanced counting rates relative to the other background segments, and an effort was made to ascertain the cause of the enhancement. This enhancement was most significant statistically at energies < 0.2 MeV, and most significant of all for B10. An energy spectrum was computed for B10 by treating it as resulting from a 'source' and subtracting from B10 a background (B8) measured ~ 30 min earlier at a higher galactic latitude. The 'B10 energy spectrum' is the product of this difference

Fig. 1 B10 energy spectrum for April 2, 1974. Data shown are energy-dependent summations of individual pulse-height channels, the F.W.H.M. energy resolution at energies near 1 MeV is 5 individual channels, for example. Bins in the figure are 4.0 F.W.H.M. in energy < 1.0 MeV and 2.0 F.W.H.M. > 1.0 MeV. The best-fit power law (see text) is also shown. All error bars shown are $\pm 1\sigma$ and are purely statistical in character.

multiplied by the appropriate correction factors (Waraven *et al.*²) for atmospheric absorption and instrumental efficiency. Figure 1 shows the B10 energy spectrum with individual pulse-height channels summed (for clarity) as indicated in the caption.

When a power-law fit was attempted to all of the channels in the B10 energy spectrum, a reduced χ^2 value of 0.894 was obtained, for 64 d.f. This fit is $(9.5 \pm 2.6) \times 10^{-3} E^{-1.4 \pm 0.1}$ photons $\text{cm}^{-2} \text{s}^{-1} \text{keV}^{-1}$, where the photon energy, E , is expressed in keV. This off-the-galactic-centre continuum has a much harder spectral index than the index of 2.78 found¹ for the galactic centre region continuum. The present continuum spectrum equals, within statistics, a prolongation of the galactic-plane spectrum measured at higher energies on SAS-2 (ref. 4), allowing for our 0.04-sr acceptance angle.

Our curiosity was aroused by the spectral feature that seems to be present (Fig. 1) in the B10 spectrum in a 1.0 F.W.H.M. interval centred near an energy of 1.16 MeV; statistically, it is the only large deviation from the power law. (The spectral lines from excited, stable nuclei that we detected¹ from the central longitudes of the Galaxy are too faint to have been detectable in this brief observation.) There is a flux of 4.2×10^{-3} photons $\text{cm}^{-2} \text{s}^{-1}$ in this interval, which extends from 1.094 to 1.274 MeV. This flux is 2.6σ above that expected from the power law. A hypothesis of a Gaussian superimposed on the B10 power law was fitted to the individual channel data, and a flux amplitude of $(3.4 \pm 1.5) \times 10^{-3}$ photons $\text{cm}^{-2} \text{s}^{-1}$ was obtained, with the hypothetical line at an energy of (1.15 ± 0.07) MeV. This yielded a reduced χ^2 value of 1.195, for 12 degrees of freedom.

Instead of B8 alone, all backgrounds except B10 were combined into a weighted mean, and the weighted mean was then subtracted from B10 to form an energy spectrum. This procedure may not have very great physical significance, because the backgrounds were measured at various zenith angles and at different times. Because the weighted-mean counting rate is slightly higher than that of B8 in this energy interval, this weighted-mean spectral line flux— $(1.9 \pm 1.2) \times 10^{-3}$ photons $\text{cm}^{-2} \text{s}^{-1}$ —is somewhat lower than the line flux given above. The feature clearly lies in a positive excess in B10, rather than a negative departure in either B8 or the weighted-mean backgrounds. Because the statistical confidence is so low, $< 3\sigma$, meaningful comments on possible broadening beyond the instrumental broadening cannot now be made.

B10 seems to have an anomalous energy spectrum. The midpoint of segment B10 occurred when the axis of the detector was pointed towards galactic longitude 345° and the galactic latitude $+5^\circ$. (The estimated error in both coordinates is $\pm 1^\circ$.) In the B10 sky region, the beam of the experiment projects on to the sky as a circle with a 6.5° radius. Because of the very limited number (~ 125) of 'source' counts, the existence of a nuclear γ -ray line at 1.15 MeV in B10 cannot here be conclusively established. If a line is indeed the physical cause of our spectral feature, then ^{44}Ca , which emits γ radiation at 1.156 MeV following the decay of radioactive ^{44}Sc , is a likely candidate. This nucleus arises from ^{44}Ti according to explosive models of supernova nucleosynthesis⁵, and was predicted by Clayton *et al.*⁶ to be the most likely galactic γ -ray spectral line to be discovered. Only supernova remnants less than a few years old should emit more intense γ -ray lines. The 1.6-MeV line flux inferred from our data equals the predicted flux⁶ for a supernova at a distance of ~ 3 kpc and an age of $\lesssim 100$ yr. These numbers do not seem unreasonable, considering that the ^{44}Ti yield 'per average supernova' need not characterise the actual yield of an unknown event in the Galaxy.

In any background runs, 2.6σ departures from a fitted continuum will occur, merely from random fluctuations. It is at least a remarkable double coincidence, however, that just when the theoretically-predicted spectral anomaly occurred just when the background measurements crossed the galactic plane. We do not claim that positive evidence for nucleosynthesis in explosive galactic events has been detected, but are reporting these results in the hope that γ -ray astronomers will be stimulated to search the B10 portion of the Galaxy for the 1.16-MeV line with more sensitive equipment. If it does arise from ^{44}Ti , the associated ^{44}Sc -decay flux will be almost constant over our lifetimes.

If ^{44}Sc is responsible for the emission near 1.16 MeV, then a flux of comparable intensity is expected near 0.511 MeV, from positron annihilation. The B10 flux measured in the 0.44–0.52 MeV interval (which includes the positronium-decay spectrum⁷), is 5.1×10^{-4} photons $\text{cm}^{-2} \text{s}^{-1}$, which is within 1σ of the contribution from the power law in this interval. Evidently the available data are consistent with the presence of radioactive ^{44}Sc , but are insufficient to establish the existence of this species within the field of view.

Optical and radio data are inconclusive regarding the model of a supernova remnant as the source of the spectral anomaly. An optical supernova remnant has been identified by Van den Bergh *et al.*⁸ at galactic coordinates of 352.05° and $+0.13^\circ$, where there is an indication of faint filamentary structure together with an extended H II region. At 408 MHz, the remnant has an angular diameter of $30'$, which implies, for a 3-kpc distance, that the age is > 50 yr. This makes the remnant probably too old to be responsible for the observed anomaly. A much smaller source of 408-MHz radiation has been identified⁹, at galactic coordinates 345.34° and $+1.43^\circ$. Although no supernova remnant has been identified optically at these latter galactic coordinates, the source can be considered a more likely candidate for the cause of the B10 anomaly, since its absolute minimum age is only ~ 10 yr.

Further observations of this region of the Galaxy should be made using more sensitive γ -ray spectrometers; they may confirm an important step forward in understanding the origins of elements.

The role of Lyman- α photons in the interstellar medium

LYMAN- α 1,216 Å photons may be produced in a variety of astrophysical situations. These photons are lost through two-photon emission on interacting with hydrogen gas, and through absorption by interstellar grains, but velocity differences between the regions of production and destruction of these photons renders their destruction by the two-photon emission process relatively inefficient¹. Grain absorption is therefore the primary loss mechanism, but since it occurs over path lengths $\gtrsim 50$ pc, there are significant interstellar Ly- α fluxes. An early theoretical estimate¹ of the interstellar flux of diffuse Ly- α photons yielded a value $\sim 6.4 \times 10^{-4}$ erg cm⁻² s⁻¹ sr⁻¹. This estimate agrees well with the first Mariner-5 and Mariner-6 observations of this flux by Barth^{2,3}, the latter giving a value of $\sim 4.9 \times 10^{-4}$ erg cm⁻² s⁻¹ sr⁻¹. Later authors^{4,5} have queried the precise fraction of this observed radiation which is genuinely extra-solar, although a significant interstellar component of Ly- α flux is generally conceded. A value in the range $1\text{--}4 \times 10^{-4}$ erg cm⁻² s⁻¹ sr⁻¹ would appear consistent with the available data. We note that the energy flux in Ly- α at the lower limit of this range is already ~ 5 times the average continuum of diffuse radiation⁶ in a 100-Å band pass centred on $\lambda = 1,425$ Å. It is also ~ 10 times greater than theoretical estimates of the continuum flux in the same waveband^{7,8}. Such a large Ly- α flux is difficult to understand if it arises from the Lyman continuum of O-B stars. Münch's original estimate¹ was based on the integrated effect of stellar chromospheres, the Ly- α photons being produced by non-thermal processes. Other likely sources of non-thermal Ly- α radiation include production in interactions of stellar winds with the interstellar medium, supernovae remnants and O VI regions such as indicated by recent Copernicus observations^{9,10}. Lyman- α photons are also expected to be formed in intercloud regions where the production of such photons provides the main cooling process. Here we tentatively adopt a Ly- α flux in the range $\sim (1\text{--}4.0) \times 10^{-4}$ erg cm⁻² s⁻¹ sr⁻¹ as being appropriate for the general interstellar medium. It is of interest that the energy density associated with the upper end of this flux range is $\sim 1.68 \times 10^{-13}$ erg cm⁻³, ~ 0.25 of the total energy density of starlight in the Galaxy. Furthermore, we note that this energy density is of the same order of magnitude as that appropriate for the galactic magnetic field, the turbulent motion of interstellar gas and the cosmic microwave background. We show here that this high Ly- α flux is of basic importance for the physics of the interstellar medium.

The electrostatic charge on grains is an important parameter which influences grain-plasma interactions, and also, probably, the heating rate of the interstellar medium. The mean equilibrium charge on grains for several likely grain materials is expected to be determined by a balance between photoejections caused by ultraviolet photons and the capture of ambient electrons^{11–13}. A mean grain potential of several tenths of a volt has been calculated¹² using the observed flux of continuum diffuse radiation in the waveband 10–13.6 eV, and for a range of interstellar cloud conditions. The mean equilibrium potential

(considering only a balance between photoejections and recombinations) is given by

$$\bar{\Phi} = kT \left\{ \left[\int_{E_i}^{\infty} F_{\gamma} Q_{abs} dE_{\gamma} / n_e v_e S \right] - 1 \right\} \quad (1)$$

where $F dE_{\gamma}$ is the radiation flux in the photon energy range E_{γ} , $E_{\gamma} + dE_{\gamma}$. Q_{abs} is the grain absorption efficiency, γ is the photoelectric yield, n_e , v_e , T are the electron density, velocity and temperature, S is a sticking coefficient and E_i is the photoelectric threshold. The value of E_i is typically ~ 6 eV for metals (including graphite) and ~ 9 eV for insulators such as silicates. In both cases these threshold energies are less than the Ly- α photon energy, $E_{\alpha} \simeq 10.2$ eV. The photoelectric yield for small particles is a factor ~ 3 higher than that for bulk material¹⁴. Taking this factor into account we adopt representative values of 0.1 for silicates and 3×10^{-3} for graphite using data of Willis *et al.*¹¹, for photon energies close to 10.2 eV. For the range of interstellar diffuse Ly- α flux adopted here the first term within brackets in equation (1) is changed by a factor of $\sim 0.4\text{--}4.3$ from its value assuming only a continuum ultraviolet flux⁶ 2×10^{-7} erg cm⁻² s⁻¹ sr⁻¹ Å⁻¹. We then obtain a mean steady-state grain potential

$$\begin{aligned} \bar{\Phi} &= \left\{ \frac{0.1 \xi \gamma}{n_e} - 0.0086 \right\} \quad V, T = 100 \text{ K} \\ &= \left\{ \frac{\xi \gamma}{n_e} - 0.86 \right\} \quad V, T = 10^4 \text{ K} \end{aligned} \quad (2)$$

where ξ is in the range 1.7–6.8 adopting $S = 1$, with the proviso that $\bar{\Phi}$ cannot exceed Φ_{max} given by

$$e\Phi_{max} \simeq E_{\alpha} - E_i$$

The values of Φ_{max} for silicates and graphite are respectively ~ 1.2 and 4.0 V for the assumed values of E_i . Setting $n_e = 10^{-3}$ cm⁻³ we obtain the following values of $\bar{\Phi}$: for $T = 10^2$ K, the potential for silicates is ~ 1.2 V and for graphite 0.04–0.20 V; while for $T = 10^4$ K, for silicates it is ~ 1.2 V, and for graphite $-0.35\text{--}1.12$ V. These calculations involved only an equilibrium between photoejection and recapture of electrons by grains. A more rigorous determination of $\bar{\Phi}$ should take account also of the capture rate of positive ions. Such a procedure does not change our estimates of $\bar{\Phi}$ for silicates. For graphite, however, slight departures occur, but these are of negligible relevance in the ensuing discussion.

For silicate grains with a relatively high photoemission yield the mean potential saturates at ~ 1.2 V in both H I clouds and intercloud regions. The close equality of this potential to $(E_{\alpha} - E_i)/e$ would preclude a significant heat source from ejected photoelectrons if all grains acquired the same potential. A stochastic distribution about a mean grain potential is, however, expected to occur¹⁴, and the r.m.s. energy of emitted photoelectrons has a non-zero value which we estimate as $E_e \simeq 0.5$ eV. The heating rate Γ_e from photoelectron emission from silicate grains by Ly- α photons is

$$\Gamma_e = \frac{\sigma n_s}{n_H} Q_{abs} \gamma E_e F_{\alpha} n_H \text{ erg cm}^{-3} \text{ s}^{-1} \quad (3)$$

where σ is the geometrical cross section, Q_{abs} is the absorption efficiency of grains, n_s is the grain density, n_H is the hydrogen density, γ is the photoelectron emission efficiency, E_e is the

mean energy of emitted photoelectrons and F_α is the flux of Ly- α photons. For $y = 0.1$, $E_c = 0.5$ eV we obtain

$$\Gamma_a = (0.38-1.5) \times 10^{-26} \left\{ \frac{\sigma n_g Q_{ab}}{n_H (6 \times 10^{-22} \text{ cm}^2)} \right\} n_H \text{ erg cm}^{-2} \text{ s}^{-1} \quad (4)$$

for F_α in the adopted range.

With $\sigma n_g Q_{ab}/n_H \simeq 6 \times 10^{-22} \text{ cm}^2$ (ref. 15) we get from equation (4) a heat input rate which is significantly higher than the corresponding rate calculated for photoemission by ultraviolet continuum photons. For graphite grains with $|\Phi| \lesssim 1.0$ V (in both cloud and intercloud regions, $y = 3 \times 10^{-3}$ and $E_c \sim 4$ eV) we find

$$\Gamma_a = (0.1-0.36) \times 10^{-26} \left\{ \frac{\sigma n_g Q_{ab}}{n_H (6 \times 10^{-22} \text{ cm}^2)} \right\} n_H \text{ erg cm}^{-2} \text{ s}^{-1} \quad (5)$$

Again with $\sigma n_g Q_{ab}/n_H \simeq 6 \times 10^{-22} \text{ cm}^2$ we obtain a heating rate which is consistent with available data on gas temperatures and cooling rates in both clouds and intercloud regions. The observed high flux of Ly- α photons could thus provide a major source of heating for the interstellar medium through their photoelectric effect on grains.

The line-centre photons of Ly- α cannot ionise hydrogen atoms, which have an ionisation threshold wavelength of 912 Å. Because of the natural width of the emitted and scattered line photons, there would be photons with energies > 13.6 eV in the line wing which could contribute to the ionisation rate of the interstellar gas. We can show, however, that the contribution of this process is not very significant compared with other mechanisms which have been proposed unless the Ly- α flux is equal to or higher than the larger value adopted in the preceding discussion.

We conclude that the recently observed large flux of diffuse galactic Ly- α photons would have an important effect in controlling physical processes in the interstellar medium. In particular the electric charge on grains, particularly silicate grains, will be primarily determined by photoejections caused by Ly- α photons. The heating of the interstellar medium will also mainly be caused by this process. If external galaxies emit an equally high fraction of their luminosity in Ly- α radiation as is indicated in our own galaxy, their effect on the intergalactic medium as well as their possible cosmological role will need to be considered. A more precise determination of the Galactic Ly- α flux is clearly a matter of paramount astrophysical importance.

Primitive grain clumps and organic compounds in carbonaceous chondrites

We show here that the physical conditions in prestellar molecular clouds favour the condensation of complex organic polymers, including amino acids, within a matrix of smaller refractory particles. Such composite grain clumps with dimensions exceeding 1 μm could be expelled along with gaseous material in protostellar cocoons, causing the widespread dispersal of biological activity in the Galaxy. We argue that grain clumps of the type considered here may be identified with μm -sized inclusions in carbonaceous chondrites.

Carbonaceous chondrites, with a carbon content of several per cent mainly in the form of aromatic polymers, and including amino acids in trace quantities, are generally believed to be among the most primitive solid bodies in the Solar System. The compaction of mineral particles with a substantial admixture of trapped volatiles must have occurred at temperatures in the range 350–500 K, with no subsequent reheating above ~ 500 K (refs 1 and 2).

Several striking isotopic anomalies have been discovered in mineral separates from carbonaceous chondrites^{3–7}. Such anomalies have tentatively been attributed to inclusions of interstellar grains which condensed in novae or supernovae explosions^{3,6,8,9}. This explanation is consistent with the occurrence of heavily irradiated μm -sized mineral separates rich in ²²Ne in the Orgueil meteorite¹⁰. The presence of μm -sized inclusions, each comprised of closely packed aggregates of grains of 100 Å (ref. 11), is also suggestive of interstellar grain clumps within carbonaceous chondrites.

An understanding of the origin of carbonaceous chondrites may have an important bearing on the early history of the solar nebula, and in particular on theories of planetary formation. The efficient adhesion of relatively cold refractory grains (for example, graphite or silicate particles) in low velocity grain-grain collisions could occur if these grains possessed mantles composed of organic polymers which are adhesive at temperatures ~ 300 K. Such organic polymers have been tentatively identified by their infrared spectral features in cometary as well as interstellar dust^{12,13}.

We argue here that interstellar molecular clouds which are the most probable sites for the condensation of polymeric mantles around grains are also likely to provide suitable venues for the formation of composite grain aggregates, by the adhesion of such coated grains in grain-grain encounters. Such grain clumps of sizes $\sim 1 \mu\text{m}$ pre-existing in the solar nebula could have served as aggregation centres for the growth of carbonaceous chondrites, perhaps representing the earliest stage of planet formation.

Large molecular clouds with masses in the range $\sim 10^4$ – $10^6 M_\odot$ are widespread in the galactic disk. Such clouds, typified by W3, OMC-2, NGC2024, Sg B2, are generally believed to be progenitors of OB associations. In a typical extended cloud of diameter ~ 10 pc, observations of molecular CO at millimetre wavelengths leads to an estimate $n_{\text{H}_2} \simeq 3 \times 10^3 \text{ cm}^{-3}$ for the smeared out hydrogen density¹⁴. More complex molecules, including HCN, H_2CO , tend to be more localised in their spatial distribution, generally associated with infrared knots, OH masers and presumably protostellar clouds. Molecular densities in such clouds are difficult to estimate. The requirement for collisional excitation of optically thin lines of H_2CO , HCN by neutral particles gives a lower limit $n_{\text{H}_2} > 10^5$ (ref. 14), but densities $\sim 10^6 \text{ cm}^{-3}$ or higher are most probably appropriate to protostellar clouds.

One may also argue that molecular clouds are not in a state of free-fall collapse¹⁵. Condensation may be slowed down by several processes, including effects of magnetic pressure, rotation and turbulence. We assume here that typical collapse times for an entire cloud, as well as for fragments within it, are of the general order of 10^4 yr. Such a condensation time, together

with the estimated total mass of protostellar clouds, gives a rate of star formation which is consistent with observations.

A molecular cloud fragment collapsing towards a protostellar situation will contain a mass fraction of $\sim 10^{-3}$ of refractory grains such as graphite, silicate and iron particles of mean radius $a_1 = 2 \times 10^{-6}$ cm. The first stages of collapse will be accompanied by accretion of organic molecules on to these grains. Since a significant mass fraction of C and O is initially in solid grains, the maximum extent of mantle growth is not likely to exceed 50% of the original radius. This gas phase accretion would proceed to effective completion on a time scale which is short compared with the estimated collapse time of $\sim 10^4$ yr. The grain radius may now be assumed to be 3×10^{-6} cm (50% increase) in accord with our earlier remarks. The precise composition of molecular mantles is uncertain, but a hybrid mixture of organic polymers is likely to ensue.

Refractory grains with such tar-like polymeric coatings tend to stick to one another in low velocity grain-grain collisions at temperature $T \approx 300$ K. Suppose $n_H (= 2n_{H_2})$ is the total hydrogen density and n_g is the grain density at this stage of protostellar collapse. Assuming an initial grain mass fraction of $\sim 1\%$, we have (for any reasonable grain specific gravity)

$$\frac{n_g}{n_H} \approx 3 \times 10^{-10} \quad (1)$$

The rate of growth of a grain clump of radius r by this process is given by

$$\begin{aligned} \frac{dr}{dt} &= \frac{\alpha n_g}{s} \left[\frac{kT \left(\frac{4}{3} \pi a_1^3 s \right)}{2\pi} \right]^{\frac{1}{2}} \\ &= \alpha n_g \left[\frac{2kTa_1^3}{3s} \right]^{\frac{1}{2}} \end{aligned} \quad (2)$$

where α is the sticking probability, s is the mean specific gravity of the grain clump material, $a_1 (= 3 \times 10^{-6}$ cm) is the radius of polymer coated grains, n_g is the number density of grains, and T is the kinetic temperature. We assume in equation (2) equipartition of energy between grains and gas and a Maxwellian distribution of grain velocities. Sticking of grains occurs by collisions during their Brownian motion with relative speeds of ~ 10 cm s $^{-1}$. With $\alpha \approx 1$, $T \approx 300$ K, $s = 1$, $a_1 = 3 \times 10^{-6}$ cm and using equation (1) we obtain

$$\frac{dr}{dt} = 8.2 \times 10^{-18} n_H \text{ cm yr}^{-1} \quad (3)$$

In the available time, $\sim 10^4$ yr, we obtain clump diameters $2r \sim 1 \mu\text{m}$ for a typical value of the molecular density $n_{H_2} \approx 3 \times 10^6$ cm $^{-3}$. Larger clumps could arise from higher density regions

The ultimate dispersal of a protostellar cocoon, including large grain clumps, may have a role in the removal of angular momentum from a central protostellar condensation, thus permitting further contraction and evolution on to the main sequence. A large fraction of composite grain clumps in such cocoons could probably survive the 'switching on' of the stars in an OB association, and they may be carried along with systematic gas flows into the general interstellar medium. Such grain clumps could indeed constitute an appreciable fraction by mass of all interstellar dust.

Large grain clumps of the type discussed here in a protoplanetary disk could also serve as accretion sites for smaller grains which condense within the disk, the process leading to the formation of planetesimals in the first instance, and eventually to planets. With a minor degree of metamorphism, such objects at

an intermediate stage of aggregation would seem to resemble the carbonaceous chondrites.

It is tempting to speculate that amino acids which have been discovered in carbonaceous chondrites¹⁵⁻¹⁷ had their origin in presolar grain clumps of the type considered here. The formation of simple amino acids (for example, glycine) is expected to take place in dense interstellar molecular clouds which may well be the cradle of life. The possible precursors of glycine, namely formic acid (HCOOH) and methanimine (CH $_2$ NH), have already been observed in dense molecular clouds, and the reaction

leading to the production of glycine is known to be exothermic. It may be relevant that glycine is the most abundant of the amino acids detected in chondrites¹⁷. Amino acids of this type, and of greater complexity may be trapped in the tarry polymeric component of our grain clumps, and be dispersed throughout interstellar space, being securely protected from destruction by ultraviolet photons by the matrix of smaller refractory grains in which they are embedded.

Comparative ionospheric and plasmaspheric electron contents from three world regions

THE radio beacon experiment¹⁻³ aboard the geostationary Applied Technology Satellite ATS-6 enables the determination of total electron content (TEC) to be made by two independent methods. The first—the Faraday polarisation rotation technique—has been widely used in obtaining TEC data. Faraday rotation is dependent on the Earth's magnetic field, and, since its magnitude is heavily weighted near the Earth, it is considered to provide integrated electron content values for altitudes below $\sim 1,500$ km. The second—the dispersive-group-delay technique, in which the phase of the modulation envelope between a carrier and its sideband is compared at two frequencies—is independent of the Earth's magnetic field and thus yields the integrated electron content between the observer and the satellite signal source. The Faraday content, N_F , and the dispersive-group-delay content, N_T , therefore, yield the TEC up to $\sim 1,500$ km and geostationary altitudes, respectively. The difference between N_T and N_F yields the content above $\sim 1,500$ km, which is referred to as the plasmaspheric content, N_P .

The ATS-6 satellite was launched into a geostationary orbit in May 1974. During phase I of its operation, when

the satellite was located at 94°W, the US Army Electronics Command operated observation stations at Fort Monmouth, New Jersey (40.18°N, 74.06°W); Richmond, Florida (25.60°N, 80.40°W); and Sao Paulo, Brazil (23.50°S, 46.50°W). In May 1975, the satellite was moved to 35°E for phase II of its operation. During this phase, the observation stations were moved to Haifa, Israel (32.87°N, 35.09°E) and Kiruna, Sweden (61.84°N, 20.41°E). In August 1976, the satellite was moved to its final parking position at ~134°W, with some of the observation stations being reactivated and others being established.

The Faraday observations were made with the 140-MHz satellite beacon emissions. The dispersive-group-delay obser-

Fig. 1 *a*, Hourly mean monthly variation of N_F at Sao Paulo, (●) (LT = UT-3); Fort Monmouth, New Jersey (○) (LT = UT-5); and Richmond, Florida (×) (LT = UT-5), during February 1975 *b*, Same as *a*, but for May 1975 *c*, Hourly mean monthly variation of N_F at Kiruna, Sweden (×) (LT = UT+1); and Haifa, Israel (○) (LT = UT+2), October 1975.

variations were made with the 140 and 360-MHz beacons modulated with sideband displacement of $\Delta f = +1$ MHz.

Figure 1*a* and *b* depict a comparative mean monthly variation of TEC measured by the Faraday technique at Fort Monmouth, Richmond, and Sao Paulo for February 1975 and May 1975, respectively. The solar zenith angle dependence of TEC is shown in the relative values of TEC recorded at the two mid-latitude stations in the Northern Hemisphere. The comparatively higher TEC values recorded at Sao Paulo, even if seasonal effects are ignored (compare Fig. 1*a* and *b*), were due to the passage of the ray path from satellite to observer through the Equatorial Anomaly region. At equatorial regions, ionospheric plasma which moves upwards from an imposed east-west electric field diffuses downwards again, but obliquely, along the geomag-

Fig. 2 Mean monthly variation of N_F at Kiruna, Sweden (at 15-min intervals), October 1975.

netic lines of force. Instead of returning to the source, the plasma arrives at two places—one to the south and one to the north of the equator. The electron content is then depleted at the magnetic equator, but is enhanced at the anomalous regions. The relatively higher TEC values for February as compared to May, confirm topside sounder results⁴ that the anomaly content crests are larger in the summer hemisphere. In addition, the ray path was in the vicinity of the South Atlantic Anomaly region where the magnetic field is abnormally weak and the loss of radiation belt particles is rapid. TEC enhancements are attributed to ionisation produced by the precipitating energetic trapped electrons that mirror low in the anomaly^{4,9}.

The comparative variation of TEC at a mid-latitude station and at a station near the auroral zone is shown in Fig. 1*c* for October 1975. The consistently higher TEC values at Haifa were due to the influence of the solar zenith angle on TEC. The passage of the ray path from Kiruna to the satellite through the density trough^{7,8} was also responsible for the observed depressed TEC values.

The mean monthly variation of the plasmaspheric electron content at Kiruna, Sweden, for October 1975 is shown in Fig. 2. The maximum content was during the day and the minimum at night, with average values between ~1.0 and ~2.0 TEC units.

Finally, the comparative variation of the plasmaspheric electron content, N_F , at Fort Monmouth and Sao Paulo during May 1975 is shown in Fig. 3. In general, the mean monthly values of N_F at both stations lay between ~1 and ~2 TEC units. The mean diurnal variation at Sao Paulo indicates that N_F had higher values during the day than during the night. The times of N_F enhancement were close to those at which the equatorial anomaly is formed and maintained⁴, and the time of N_F depression corresponded to

Fig. 3 Mean monthly variation of N_F at Fort Monmouth, New Jersey (○); and Sao Paulo, Brazil (●), May 1975.

disappearance of the anomaly. It is therefore possible, that during the formation of the anomaly and during its maintenance, the plasmaspheric and the ionospheric electron densities are increased.

Meridional interactions between rainfall and surface pressure

We have been investigating temporal variation in rainfall over a part of the Southern Hemisphere^{1–4}. In view of the current concern regarding food production and future climatic change (for example, a shift in the westerlies over the Northern Hemisphere) this area of research is of some importance. The recent drought and resulting famine in the Sahel^{5–7} also shows that stresses in one hemisphere can be a burden on the food resources of the other. Until now, however, quantitative interactions between rainfall and the general circulation have not been given; here we show first, that there are structural relationships between annual rainfall over Southern Africa and the month to month variation in the mean latitude of the surface high pressure belt, L (ref. 8). The evidence adds credibility to findings related to the temporal variation in rainfall^{3,4}. Second, a means of forecasting annual rainfall totals is shown to be feasible. The method used in the analysis is neither geographically restricted, nor applicable to rainfall only.

A linear step-wise regression analysis was first carried out on 30 yr of rainfall data and the associated value of L (1942–71). In this way the independent variables, L , can be quickly assessed for their importance in predicting rainfall. The analysis was carried out on the total annual rainfall for the regional temporal series A as defined in refs 2 and 3. This time series represents the rainfall over an area whose middle is at $\sim 27^\circ\text{S}$.

We will give the months in the order they were taken into the regression. When the total rainfalls were regressed on the monthly L values, January and September were included. The fit of the regression is significant at the 2.5% level. To check for some sort of organisation in rainfall totals unaccounted for by the regression, a plot of the residuals was carried out. There is evidence of an oscillatory pattern in the residuals, the period being 2–3 yr. This may

be related to the quasi-biennial oscillation which is now a well accepted geophysical phenomenon⁹.

A regression of rainfall totals on L values during months in the preceding year resulted in the inclusion of June and March. The fit is significant at the 1% level. A plot of the residuals again indicates a wave-like pattern with period in the range 2–3 yr.

Mean latitudes, L , for one year, together with those for all months in the previous year, were then included in the regression, bringing the L -value for January of the year in question as well as June, March and February of the preceding year. The fit of this regression was significant at the 1% level. The predictors are not just the addition of the two sets from the previous regressions, which results from the use of the multiple correlation coefficient between rainfall and L (ref. 10).

As a forecasting equation this particular grouping of variables accounts for 52% of the total variance in annual rainfall. This is an encouraging result. A plot of the residuals against time indicated that a linear term was required in the regression. Such a term was added to the set of predictor variables and the analysis repeated, with the linear trend as the fifth term, or that of least importance. The

Fig. 1 Showing the rainfall residuals in a regression on the mean latitude of the surface high pressure belt for January in a current year, and June, March and February of the preceding year; the linear trend has been removed.

total variance now accounted for 58% of the whole. The residuals still exhibited an oscillatory pattern (Fig. 1) and they were therefore submitted to spectral analysis. Because of the short length of the series (30 terms) Burg's maximum entropy method was used¹¹. The spectrum shows excessive variance associated with periods of 5.88, 3.03 and 2.22 yr (Fig. 2).

A trigonometric function was fitted to the residuals, and resulted in the use of periods of 6.0 and 3.0 yr. The shortest period was considered too weak to include in the equation. The additional variance accounted for by this step was significant at the 1% level. In all, just over 84% of the total variance in rainfall has been accounted for, and the standard errors for forecasts is 6 cm, which is quite acceptable.

The final forecasting equation therefore contains as predictor variables:

(1) The mean latitude of the surface high pressure belt

Fig. 2 Showing the spectrum of residuals when annual rainfall totals are regressed on the mean latitude of the surface high pressure belt for January in a current year, and June, March and February of the preceding year.

for January of a current year, with regression coefficient equal to -15.24 .

(2) As above, but for June, March and February of the preceding year, with regression coefficients -9.31 , 19.41 and 13.96 respectively.

(3) A linear term in time with regression coefficient 3.69 .

(4) A constant term equal to -422.82 .

(5) A trigonometric function having periods of 6.0 and 3.0 yr with cosine and sine coefficients 7.28 and -49.03 , and -47.82 and 39.04 respectively.

"Upper Jurassic" sediments of South Africa

MARINE sedimentary rocks exposed near Knysna in the Cape Province of South Africa were assigned to the Upper Jurassic on the basis of a fragment of an ammonoid and seven previously undescribed species of ostracod¹. A more thorough examination of the microfossils in these rocks indicates that this assignment was erroneous and that the beds are of Early Cretaceous, probably Hauterivian, age². This age determination was based on identification of fifty species of palynomorph, five species of calcareous nannofossil, and twelve species of foraminifera. Both the palynomorphs and the foraminifera indicate a correlation with the upper part of the Sundays River Formation, a unit reliably dated as Valanginian to Hauterivian. The nannofossils indicate a Valanginian or Hauterivian age.

Ordinarily, a slight error in the age of a few small exposures in a remote portion of the globe would not be a matter of significance. These were the only marine sedimentary rocks of Jurassic age known from South Africa, however, and their age was considered to be important for timing the break-up of Gondwanaland³. In a very superficial search of the literature, we noted numerous citations of the Jurassic age (see refs 3-7). It was therefore thought desirable to bring to the attention of those concerned with the problems of Gondwanaland rifting that there are no marine sedimentary rocks of known Jurassic age in South Africa.

Cyanophycean nature of stromatoporoids

STROMATOPOROIDS are calcareous fossils abundant in many Palaeozoic (mainly Silurian and Devonian) shallow-water carbonate sediments. Forms ascribed to stromatoporoids have also been reported from Mesozoic epicontinental and tethyan carbonate deposits¹. The nodular, tabular or cylindrical and, generally, vertically laminated calcitic skeletons of stromatoporoids (Fig. 1a), ranging in size from a few mm to >1.0 m, are internally formed of curved plates, short or long pillars and vertical walls. A characteristic feature of many stromatoporoids are stellate structures, a few mm to 6-7 cm across, termed astrorhizae. In spite of 150 yr of investigation the systematic position of stromatoporoids is still controversial. They have been variously interpreted as foraminifers, sponges and hydrozoans^{2,3} with discussion on the latter two groups bearing particularly on the interpretation of the skeletal morphogenesis^{4,5}. New discoveries⁶ of peculiar modern sponges with mixed calcareous and spicular siliceous skeletons (Sclerospongiae) reopened discussion on the relationship of this group to stromatoporoids, initiated at the beginning of the century by Kirkpatrick^{7,8}. Hartman and Goreau's suggestion⁹ has been taken up and supported by Stearn^{5,10} and Wendt¹¹. Stearn argued that stromatoporoids should be recognised as a separate subphylum of the Porifera. Wendt similarly regarded stromatoporoids as

Fig. 1 *a*, Vertical axial section of the distinctly laminated skeleton of *Stromatopora undata* Riabinin from the Upper Devonian of central Poland; *b*, *c*, enlarged fragments of the same skeleton in vertical (*b*) and tangential (*c*) section showing granular microfabric representing permineralised aggregates of coccoidal cells, transmitted light.

a conservative order of the Calcispongiae closely related to the Pharetronida. Spicules, however, are quite unknown in stromatoporoids and the discovery of fossil (Cretaceous) sclerosponges with preserved spicules^{12,13} shows that their absence cannot arise from diagenetic dissolution as Hartman and Goreau suggested. Interpretation of the astrophorizae is critical to any discussion of stromatoporoid affinities. As poriferans, the astrophorizae become traces left by the sponge exhalant canals, or as hydrozoans they are structures homologous to coenosarcial stolons (hydrohorizae). Kaźmierczak¹⁴ rejected both interpretations and argued that astrophorizae are traces of foreign organisms probably commensal or mutualistic with stromatoporoids. The new observations reported here modify but confirm this.

Discovery of unusually well preserved astrophorizae reveals the nature of stromatoporoids as permineralised colonies of coccoid cyanophytes homologous with modern and fossil

stromatolites. The astrophorizae occur in *Parallelopora* aff. *planulata* (Hall and Whitfield) obtained from the Upper Devonian (Frasnian) limestone of the borehole Niesiołowiec IG-1 (south-eastern Poland) at a depth of 1,330–1,336.4 m. In contrast with previously known astrophorizae, which appear either as a stellate system of furrows on the surface of the skeleton (Fig. 2*a*) or as radiating tubes with rare cross partitions filled by sparry calcite in thin section (Fig. 2*b*), the astrophorizae in *P.* aff. *planulata* are almost wholly filled by granular calcareous material (Fig. 2*c*). In transmitted light this is distinctly darker than the surrounding skeleton against which it sharply abuts. At many points, however, the skeleton passes into the dark astrophorizal infilling. The structural uniformity of the astrophorizal infilling and the surrounding skeleton is also stressed by the similar size and outline of the interskeletal spaces in both tissues. Where the dark granular material is absent the astrophorizal canals are filled by spar as is generally the case (Fig. 2*d*, arrowed). Under higher magnification the clotty infilling of the astrophorizae can be recognised as aggregations of spherical and subspherical bodies, slightly darker peripherally. Individual bodies have an average diameter of 10–40 μm and are distributed irregularly, rarely forming short pseudofilamentous rows (Fig. 2*e*, arrowed).

The globular bodies from the astrophorizal infillings and the granules of the surrounding skeleton are essentially similar, the main difference lying in the higher crystallinity of the

Fig. 2 *a*, Large astrophorizae on the surface of the Middle Devonian stromatoporoid *Trupetostroma* sp.; *b*, astrophorizae in tangential thin-section of Silurian *Plectostroma* sp. showing tubes filled by sparry calcite, transmitted light; *c*, *d*, tangential thin-sections through astrophorizal tubes in the Devonian *Parallelopora* aff. *planulata* (Hall and Whitfield) filled by dark granular material which is locally absent (arrowed), transmitted light. (Note also cross sections (t) of intergrown syringopoid tabulate corals); *e*, enlarged fragment of astrophorizal infilling showing subcircular outlines of permineralized common sheaths of aggregates of coccoidal cells forming rare, short chains (arrowed), transmitted light; *f*, a colony of the extant *Entophysalis samoensis* Wille built of *Gloeocapsa*-like aggregates of cells (*g*) enclosed in common sheaths (after Wille).

latter, which results in their higher transparency and indistinct outlines. Granular microfabric is common in stromatoporooids and has been referred to as cellular, melanospheric or maculate microstructure¹⁵ (Fig. 1b and c).

The spheroidal bodies composing the infillings of astrophorizae can be identified as remnants of permineralised aggregates of cells of coccoid cyanophytes. Identical structures have been observed in modern calcareous stromatolites formed by entophysalidacean blue-green algae^{16,17}, where they form colonies composed of numbers of cells arranged in pseudofilamentous strands (*Entophysalis*) or are distributed irregularly^{18,19}. Such cells, surrounded by mucilage sheaths, are usually found within greatly enlarged common mucilage sheaths enclosing *Gloeocapsa*-like aggregates (Fig. 2f, g). It has been only recently observed¹⁷ that during permineralisation with calcium carbonate it is the tough outer sheaths which envelop particular aggregates of cells that are most resistant, and commonly remain as the only trace of the primary structure of a colony. Similarly, resistant sheath material has been observed in Late Precambrian pleurocapsalean cyanophytes from silicified dolomite²⁰. The filamentous pattern of astrophorizal canals is reminiscent of linear cell masses of some siphononematacean cyanophytes during the stigonematoides growth stage²¹. The granular microfabric of the astrophorizae and the surrounding skeleton indicates that the same or very similar cell aggregates took part in the formation of both.

There are two questions related to the last statement: first, why, having the same microstructural character as the surrounding skeleton, the astrophorizal infilling is darker and less crystalline, and second why the astrophorizae are usually found empty? An explanation to the first question may lie in the colony organisation of extant coccoid cyanophytes in which *in situ* germination of gonidia, endo- or exospores or even groups of nannocytes leads to the formation of new colonies continuing growth as an integral part of the old colonies^{18,19,22}. *In situ* germination of spores is particularly common in some pleurocapsalean cyanophytes²⁰. There is little doubt that astrophorizae represent such *in situ* developed new coccoid colonies, but with significantly reduced permineralisation potential compared with the parent colony. The modern counterpart of the stellate pattern of astrophorizal canals can be found in radially filamentous juvenile stages of such colonial coccoid cyanophytes as *Oncobrysa rivularis* or *Pleurocapsa minor*²¹. As in astrophorizae, the filamentous aggregates of cells in these forms grow first more or less parallel to the substratum branching dichotomously or trichotomously and then, as a result of tetrachotomy, grow upwards losing their filamentous habit. Empty astrophorizal canals represent weak or absent permineralisation of the young colonies, insufficient to protect the organic matter against decomposition. Differences in the degree of permineralisation of different growth stages within the same coccoid strains means active control of the mineral precipitation at least by the young colony. More detailed studies on the organisation and mode of formation of modern coccoid cyanophytes, especially those encrusted by calcium carbonate, are needed before a complete explanation of stromatoporoid biology can be given.

Removal of the Stromatoporoidea from the animal kingdom to the Cyanophyta requires the complete re-evaluation of their taxonomy, palaeobiology and geological significance. This and a more extensive discussion of the new data presented here will follow in a forthcoming paper. The main conclusions are:

(1) stromatoporoids represent permineralised colonies of coccoid cyanophytes closely related to those associated with fossil and modern calcareous stromatolites (cyanophytic stromatoids), formed by *in situ* precipitation of calcium carbonate,

(2) stromatoporoid stromatolites are the Phanerozoic continuation of the Precambrian calcareous stromatolites in

which coccoid communities also had a considerable role^{23,24}.

(3) stromatoporoid stromatolites with their internally differentiated structure, and clear evolutionary tendencies⁴ may contribute significantly to the systematics and correlative value of Precambrian stromatolites,

(4) the very high permineralisation of stromatoporoid coccoid cyanophytes is comparable only with calcium carbonate encrusted cyanophycean communities known from modern freshwater and brackish environments²⁵. This suggests that the epicontinental seas occupied by stromatoporoids had other than present-day salinities, a conclusion supported by the recently reported²⁶ *in situ* association of *Amphipora* with non-marine volvocacean algae.

Palaeognathous bird from the Cretaceous of Central Asia

Two skulls of an unquestionably palaeognathous bird were found by the Polish–Mongolian Palaeontological Expedition to the Gobi Desert¹. Both specimens originate from the same locality, the beds being referred to as Barun Goyot Formation (?Campanian²). One skull, badly damaged, has been described as *Gobipteryx minuta* and the new order Gobipterygiformes has been allocated tentatively to the Palaeognathae³. Examination of the second, better preserved, although incomplete skull has now confirmed this allocation. Thus, *Gobipteryx* is the oldest known palaeognathous bird, the earliest hitherto recorded fossils of this group being of Eocene age⁴. I estimate the skull of *Gobipteryx* to be 45 mm long, so that the bird was roughly the size of a partridge.

Gobipteryx displays palaeognathous affinities both in the pattern of the palate and the features directly related to the ratite rhynchokinesis⁵ (Figs 1 and 2). Anteriorly the vomers are fused and closely approached by the maxillopalatines. At the rear, the vomers diverge gradually and articulate suturally with the pterygoids, which have a medial socket near the posterior end, obvious for a basipterygoid articulation. The palatine articulates suturally with the outer margin of the pterygoid, so that parasphenoidal contact is ruled out. As far as it preserved, the palate of *Gobipteryx* satisfies all the criteria of the palaeognathous type⁶. The most

striking rhynchokinetic feature is the anterior extension of the nasal opening together with the lack of the connection between the nasal and the maxilla. The free-ending, ascending process of the maxillopalatine, present in *Gobipteryx*, elsewhere occurs only in some ratites (*Rhea*, *Casuarius* and *Dromaius*). Moreover, the loose contact between the nasal process of the premaxilla and the premaxillary process of the nasal, clearly seen in *Gobipteryx*, occurs in all ratites and some members of the Tinamidae. The common occurrence of such a palatal and rhynchokinetic condition provides new evidence of the coupling of these two characteristics⁶.

In some features *Gobipteryx* seems to resemble the Australian ratites, in particular its palate structure is similar to that of *Casuarius*: the posterior bifurcation of the vomers is very deep, with their lateral edges lying more ventrally than the medial ones; the pterygoids widen distinctly in the region of the palatine articulation; the palatine articulates mostly if not exclusively with the pterygoid; the outer margin of the palatine is much thicker than the inner blade and projects ventrally. In *Gobipteryx* the palatine is posteriorly enclosed in the slight anterior bifurcation of the pterygoid, with the small outer tine projecting antero-laterad. Such a pterygoid bifurcation was thought to be unique in *Apteryx*⁷. Thus, *Gobipteryx* shares some characteristics with both *Casuarius* and *Apteryx*⁸ and unless it is

Fig. 1 *Gobipteryx minuta* Elzanowski 1974. The second skull. a, Dorsal view; b, ventral view; c, left lateral view; d, right lateral view ($\times 2.5$).

Fig. 2 *Gobipteryx minuta* Elzanowski 1974. Partial restorations of the skull. a, Ventral view; b, rostral part in lateral view. ch, internal naris; mxa, ascending process of the maxillopalatine; mxp, maxillopalatine; np, premaxillary process of the nasal; pl, palatine; pn, nasal process of the premaxilla; pt, pterygoid; q, quadrate; qor, orbital process of the quadrate; v, vomer.

assumed that these are primitive characteristics of the Palaeognathae as a whole, they might indicate a closer relationship between the Casuariformes and Apterygiformes, as suggested already^{8,9} though later challenged¹⁰.

The mandibular articulation of the *Gobipteryx* quadrate is atypical of the Palaeognathae, and resembles that of the pigeons: it is bicondylar without any structure corresponding to the posterior condyle. Such a quadrate is also clearly similar to that found in some smaller theropods, such as *Gallimimus*¹¹ or *Dromaeosaurus*¹², with the orbital process corresponding well to the pterygoid flange of the dinosaurs.

Palaeognathous birds are commonly thought to be of southern origin¹³⁻¹⁵, although this view was challenged for struthionids and aepyornithids¹⁶. Moreover, the dispersal of palaeognathous birds between the Old and New Worlds is explained only by the Gondwanian connections¹³. The Asiatic origin of *Gobipteryx*, the oldest known representative of the group, gives some evidence in favour of the northern dispersal. If migration across Beringia was possible for small mammals¹⁷, it would be the more so for birds although the flying ability of *Gobipteryx* remains a vexing problem.

I thank Professor Z. Kielan-Jaworowska for help and supervision.

Rivalrous texture stereograms

THE two eyes receive slightly differing views of the world and it has been known since the invention of the stereoscope, 140 yr ago, that these slight differences are utilised by the visual system for stereopsis—the perception of the relative depths of objects on the basis of binocular disparity. The central theoretical problem in stereopsis is simply stated: how is disparity information extracted from the two retinal images? We examine here various possible answers to this question.

The most obvious possibility, and historically the first to be considered, is that the brain identifies objects in each eye's image, notes their different relative locations and computes stereopsis accordingly. But a monocular object recognition stage is emphatically not a requirement for stereopsis. This has been clearly demonstrated by the random-dot stereograms of Julesz¹. These stimuli show that stereopsis can be perceived even when the two eyes receive

Fig. 1 Rivalrous texture stereogram (after Tausch²). Binocular fusion of the two halves of this figure results in the perception of relative depth (stereopsis) between two circular patches.

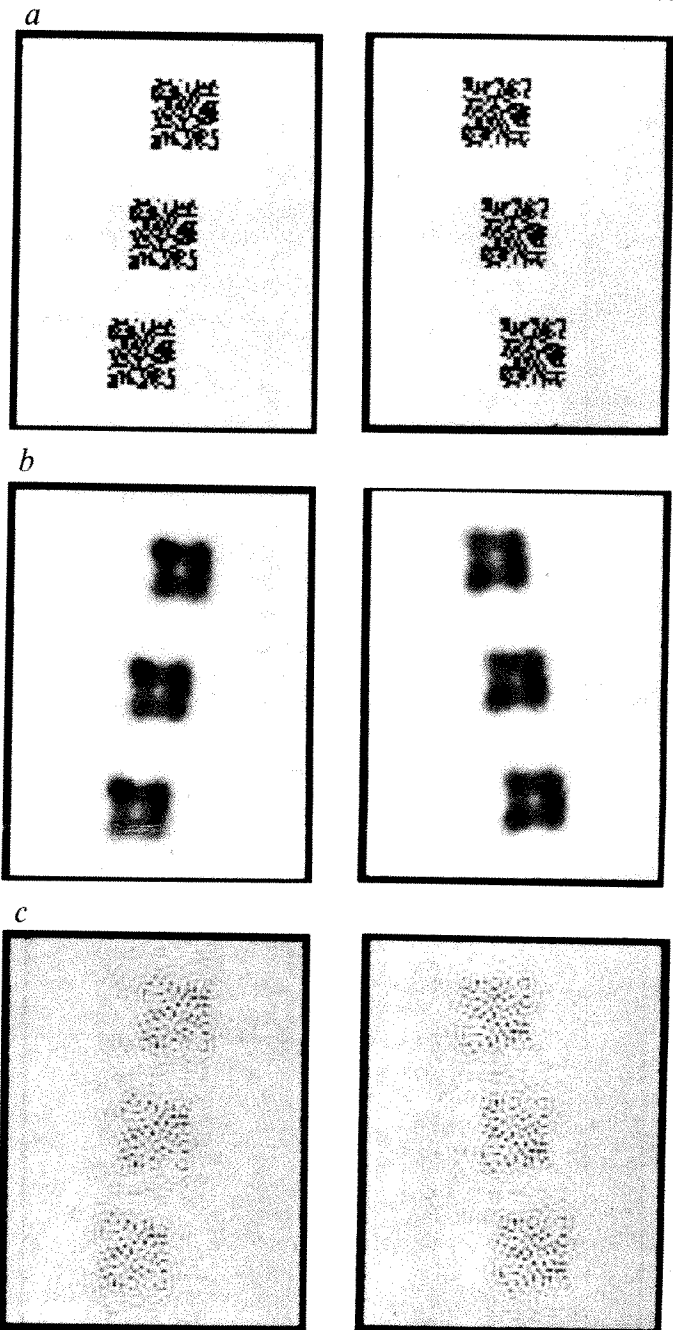

Fig. 2 *a*, Rivalrous texture stereogram in which three squares are seen to lie in different depth planes after binocular fusion although their textures are rivalrous. Each texture is an upside-down mirror image of the corresponding texture in the other field. This renders each pair of textures effectively random as far as binocular fusion is concerned, and hence rivalrous, and yet ensures that the left and right images have identical power spectra. The central squares have zero disparity with respect to the outer frame whereas the upper and lower squares have crossed and uncrossed disparities respectively. Presenting three squares in this way facilitates judgements of stereopsis, particularly in the relatively difficult circumstances of rivalrous texture stereograms, because if stereopsis is present not only do the squares appear in different depth planes but they also tend to appear vertically aligned. It is a methodological improvement over single-square figures³, in which it is not always easy to know whether the segregation of the square from its ground is presenting a masking depth cue which gives a depth impression independently of stereopsis. *b*, Low pass filtered version of (*a*) which contains only spatial frequencies below 1.0 cycle per degree if viewed from five times picture height. *c*, High pass filtered version of *a* containing only spatial frequencies above 4.0 cycles per degree. The original stereograms were prepared using a full-tone facsimile picture receiver monitored with a UDT photometer and viewed with back illumination. Photographic and printing processes inevitably introduce some spectral distortion from the originals but the various stereo effects which can be observed are faithful nonetheless.

random textures in which are embedded disparate forms completely hidden to monocular view but which nonetheless appear in depth due to the fact that their random textures are correlated in the two fields. This finding has led Julesz to conclude that there must exist stereopsis mechanisms which operate by effecting a 'low level' point-for-point matching of the two retinal images.

Given then that monocular object recognition is not a necessary precursor of stereopsis, it is interesting to ask whether it is a sufficient precondition. Consider Fig. 1, for example. This 'rivalrous texture stereogram'² successfully presents disparity depth cues by means of 'object' information even though there is only random correspondence between the left and right images of these objects at the level of fine texture elements. It is tempting to conclude from this demonstration that, as a 100% point-for-point matching of the left and right images of the objects is clearly impossible, a stereopsis mechanism sensitive simply to monocularly-discriminable shapes, irrespective of their precise detailed textures, must be at work and that therefore the monocular object recognition of disparate objects is indeed a sufficient basis for stereopsis³.

Fig. 3 Stereogram comprised of the left half of Fig. 2b and the right half of Fig. 2c. Stereopsis is impossible.

One conceivable way of accounting for the stereopsis of Fig. 1 in point-for-point terms, however, is to suppose that point-for-point matching follows a stage of spatial frequency filtering. Thus the disparity information carried by the objects might be extracted by point-for-point matching in a 'stereopsis channel' tuned to low spatial frequencies; while at the same time other stereopsis channels tuned to higher spatial frequencies, and thus sensitive to fine texture details, are in states of rivalry. This possibility is supported

Fig. 4 Stereogram comprised of random textures with no overlapping spectral content. Right hand: squares, 1.33 to 1.75 cycles per degree; surround, 4.0 to 5.25 cycles per degree. Left hand: squares, 2.3 to 3 cycles per degree, surround, less than 1 cycle per degree. Stereopsis is impossible.

by the demonstrations of Julesz and Miller⁴ which show that in random-dot stereograms depth can indeed be mediated by one spatial-frequency-tuned channel while others remain in rivalry.

We have tested this explanation using low and high bandpass filtered versions of the rivalrous texture stereogram shown in Fig. 2a. Figure 2b (low pass) and c (high pass) would selectively stimulate low and high spatial-frequency-tuned channels, respectively. As predicted, stereopsis is clearly present in the low bandpass filtered stimulus. Stereopsis, however, can also be established without difficulty in the high bandpass stereogram. This result shows that the idea of only low spatial-frequency-tuned channels being capable of mediating the depth seen in rivalrous texture stereograms is false: such channels would

Fig. 5 a, Stereogram in which both squares and their surround are comprised of rivalrous textures (after Ramachandran *et al.*⁵). Rivalrous textures have been created as for Fig. 2. b, Low pass (1 cycle per degree) version of (a). c, High pass (4 cycles per degree) version of (a). Stereopsis is possible in (a) and (c) but with greater difficulty than in Fig. 2c.

not be active in the case of Fig. 2c and yet stereopsis is present.

The fact that stereopsis can be perceived in Fig. 2c suggests once again the operation of a 'monocular-object' stereopsis mechanism which is picking out the monocularly-visible texture boundaries of the squares and ignoring the fact that the details of the left and right textures do not match. It is therefore instructive to ask whether it is possible to obtain stereopsis by combining the left half of Fig. 2b with the right half of Fig. 2c. The squares in each of these half stereograms are of course perfectly visible monocularly and if there existed a mechanism capable of being driven by gestalts formed by texture contours³, then such a combination should surely produce stereopsis. Figure 3 represents this combination and we find stereopsis impossible. The two fields are extremely rivalrous. This result suggests that stereopsis can be obtained from rivalrous texture stereograms only if there is spectral overlap in the two halves of the stereogram, irrespective of the monocular visibility of the texture contours themselves. This conclusion is further supported by Fig. 4, which presents squares composed of rather less markedly different spatial frequencies in the two fields than Fig. 3 and sets them in surrounds also differing in spatial frequency. Again stereopsis is impossible, in spite of the existence of clearly discriminable and disparate monocular gestalts.

Fig. 6 Rivalrous texture stereogram in which the squares are comprised of spatial frequencies above 3.5 cycles per degree and in which the surround is comprised of spatial frequencies below 1.75 cycles per degree when viewed from five times picture height. Stereopsis is easy to obtain.

Figures 3 and 4 suggest that the notion of spatial-frequency-tuned stereopsis channels is valuable when considering rivalrous texture stereograms. But if such channels are to explain the stereopsis of Fig. 2c, and these channels are to be considered as involved in a process of point-for-point matching, then an account must be offered of how such channels could output stereopsis for Fig. 2c even though the textures of its squares have only random correspondence.

We submit that Fig. 2c has, for a high spatial frequency channel, what might be called partial point-for-point correspondence, rather than no correspondence whatsoever. First, note that the almost uniformly grey (d.c.) surrounds to the squares in Fig. 2c would not produce above-threshold activity in high spatial-frequency-tuned units. An array composed of such units would, quite simply, be 'blind' to these surround areas and not transmit forward any information about bright or dark points for point-for-point stereopsis processing. (The fact that our original high spatial frequency filtering produced these grey surrounds could be misleading here. If Fig. 2c is considered not as a stimulus but as a representation of activity in a high spatial-

frequency-tuned channel when stimulated by Fig. 2a, then it must be remembered that the grey level in this representation is the baseline or noise activity level, with above threshold departures from this level, bright or dark, being the only transmitted information to later stages of processing. That is, the white points in Fig. 2c can be regarded as reflecting above-threshold activity in high spatial-frequency-tuned neural units with on-centre/off-surround receptive field profiles, the black points as above-threshold activity in similar units with off-centre/on-surround profiles and the grey points as below-threshold activity in both these kinds of units.) Second, consider the possible matches which could be established for brightness points lying within the 'disparate' areas of the squares (that is, those areas 'confronted' with d.c. surround in the other field of view). These points could find no matches whatsoever at non-disparate locations, simply because the d.c. would not produce any above-threshold activity at these locations. If they are to find a match at all it would have to be a disparate one. And the possibility arises that a sufficiently large number of such matches occurs for stereopsis to be generated. Of course, there will never be a state of perfect point-for-point matching obtained for these areas, due to the inherently random selection of the two textures forming the squares. Nonetheless, a state of partial point-for-point correspondence does obtain and, as Julesz¹ (pages 271-275) has amply demonstrated, partial correspondence is an adequate basis for stereopsis. Moreover, there is no reason, in principle, why a point-for-point mechanism should require perfect correspondence as a *sine qua non* of its successful operation.

We report elsewhere³ a more detailed exposition of this idea and a development of Julesz's dipole model of stereopsis¹ which would be capable of providing the hypothesised binocular matching. At present we simply note some evidence which supports the idea in general terms.

Our explanation of the stereopsis of Fig. 2c depends crucially on there being no matches available in the surround areas. This leads naturally to the following question: what would happen if both the squares and their surrounds were composed of rivalrous textures? Such stereograms have already been devised³ and an example is shown in Fig. 5a. The squares of this stereogram are discriminable simply by virtue of the fact that their texture elements are half the size of those in the surround. Stereopsis from this stereogram is poor and unstable, as the inventors of this stereogram note and as the reader may judge. It is certainly of greatly reduced quality compared with the stereopsis from Fig. 2a-c. Figure 5b and c presents respectively low and high pass versions of Fig. 5a. As would be expected, the squares do not exist as monocularly-discriminable entities in either half of Fig. 5b. Fusion of this stereogram usually results in complete rivalry although we find that some observers occasionally report depth impressions relating to certain blobs which happen, through the random processes of manufacture, to have *ad hoc* and fortuitous disparities. In Fig. 5c the squares do exist as monocular entities although in a much attenuated form when compared with the squares in Fig. 2c. We find that stereopsis from this figure is possible although it is not obtainable as readily as in Fig. 2c, nor is it as stable. These impairments, caused by including a rivalrous surround, are exactly what would be expected given our general interpretation because local processes serving the squares in Fig. 5c can now obtain a better degree of matching with their surrounds than can the squares of Fig. 2c. Of course, given that the squares in Fig. 5c are still characterised by slight brightness differences from their surrounds, one would still predict that stereopsis should be possible because square/square matches will have a slight edge over square/surround matches. Nonetheless, because the brightness differences characterising the squares are not very marked, this superiority would not be as great as in Fig. 2c—hence the

fact that stereopsis can be obtained in Fig. 5c but in an impaired form.

One interesting prediction that can be drawn from our analysis of Fig. 5a is that stereopsis should be clear and easy to obtain from stereograms with rivalrous texture surrounds if the spectral content of the surround is sufficiently different from that of the squares. In such cases, the spatial frequency tuning of the channel dealing with the squares will result in this channel effectively dealing with a uniformly grey surround (as in Fig. 2b and c). Figure 6 presents a stereogram of this type and it produces clear stereopsis, as predicted.

The important conclusion deriving from our analysis is that stereopsis in rivalrous texture stereograms can be explained by spatial-frequency-tuned stereopsis channels without any need to involve more complex stereopsis mechanisms incorporating monocular object recognition.

We thank Dr O. Braddick for his helpful comments.

Role of stimulus environment and duration of processing in long term memory

A MAJOR concern of current memory research is to identify how information is encoded and transferred from short term memory (STM) to long term memory (LTM)^{1,2}. It has been reasoned that while an item remains in STM, it can be maintained through rehearsal; as a consequence, the corresponding LTM trace is built up. Thus, one may postulate that the adequacy of an item's registration in LTM is a positive function of the length of its stay in STM. Such a mechanical and simplistic account of memory has been challenged by a series of experiments which showed that when short term storage times were measured, these times did not predict long term retention^{3,4}. We report here an experiment which manipulated the processing time as well as the processing context and showed that the processing time had differential effects, sometimes beneficial, sometimes harmful, and sometimes neutral, on an item's long term retention, depending in which type of processing context the item was embedded. Such results argue for a perceiver-environment interactive theory of memory.

To minimise the difference between subjects' mnemonic strategies, the present experiment used an incidental-learning paradigm—that is, the subjects were not informed about the recall test until the very end of the experiment. Instead, they were told that the experimental task was a target-search task and were made to believe that our interests were the accuracy and the speed of their search. In fact, the experimental task was similar to the visual search task used by Neisser and Beller⁵ except for the final unexpected free recall test. In general, the subject was required to hold a target word in his memory and then to scan through a search list until the particular target word was found. By manipulating the target position within the search list and the nature of others in the list, we were able to vary the processing duration as well as the stimulus environment. In the present study, there were four different list structures and three different target positions, forming

a 4 × 3 factorial design with both variables as within-subjects measures.

The four list structures were made up in the following ways. To illustrate, let the target word be TABLE. For the phonemic-similar (PS) condition, all other list words were phonemically similar to the target—for example, STABLE, CABLE, MAPLE. For the semantic-similar (SS) condition, all other list words belong to the same semantic category as the target word—for example, CHAIR, SOFA. For the random (RAN) condition, all other list words were randomly selected from the Thorndike-Lorge's high frequency words. Finally, for the nonsense (NON) condition, all other list items were nonsense but pronounceable letter strings with length ranging from three to five. The target words were always embedded in list position 3, 9 or 15. The search lists were always 20 items typed (double spaced) vertically in a column. The subjects were 40 undergraduate students enrolled in an introductory psychology course at the University of California (Riverside), and were tested individually.

The subject was instructed to search the list from the top to the bottom, using a pencil to direct his attention to each word. The subject was instructed to search for the target word as quickly and as accurately as possible, and to place a check beside the target word as soon as it was found. The experimenter recorded the search time for every word with a stop watch. Two practice trials with numbers preceded the experimental task of 12 target searching trials. After the last searching trial, the subject was asked to fill in a questionnaire which included some autobiographical data—for example, name, address, phone number, and so on, for about 2 min. An unexpected recall test was then administered. The subject was asked to write down as many target words as he could in any order he preferred. This recall interval was fixed at 2 min. A post-experimental interview revealed that no subject had anticipated such a "tricky" test.

Fig. 1 The subject was asked to hold a target word in his memory and then to scan through a list of words until that particular target word was found. At the end of 12 such visual search trials with 12 different target words, an unexpected recall test for all the target words was administered. Mean percentage recall of the target words was plotted in this figure as a function of the processing time and the processing context. The length of the processing time was manipulated by placing the target word at one of the three positions (that is, 3, 9 and 15) within the search list. The processing context was manipulated by varying the nature of the search list: ●, all other words in the search list were phonemically similar (PS) to the target word; ▲, all other words in the search list were semantically similar (SS) to the target word; ■, all other words in the search list had no apparent relation to the target word (RAN); ◆, all other items in the search list were non-words (NON) made up with nonsense syllables.

The results of the experiment are summarised in Fig. 1. Mean percentages of correct recall in various list conditions were plotted as a function of the target position. It is clear that the duration of processing has differential effects on the item's long term retention, depending on the stimulus environment in the processor at the time of processing the item. Statistical tests (ANOVA) substantiated the interaction between target position and list condition ($F(6, 234)=4.78, P<0.01$).

The first striking aspect of the data depicted in Fig. 1 is the fact that when the target was embedded at position 3, the PS list condition produced the best recall performance compared with the other three conditions (all P values <0.05 with Tukey's test) which did not differ from one another. This is a very intriguing finding. Most current memory theories would predict that since the item would be better retained in a non-interfering environment than in an interfering context, recall performance would be worse in the PS condition where the processor is filled with acoustically similar items. But the data showed that this prediction holds only at position 15. The relative superiority of the PS condition at positions 3 and 9 is difficult to account for by current memory theories.

From the viewpoint of a perceiver-environment interactive model, however, the superiority of the PS condition at position 3, followed by a gradual decline at position 9 and 15, can be readily explained. According to Neisser and Beller⁵, in a search task the subject needs only to hold a phonemic representation of the target word while he is searching the list. The immediate match between the temporarily held representation and the acoustically similar environment pushes the recall level up about 20%. This facilitating effect of a phonemically similar environment suggests that an acoustically similar sound helps to confirm and establish a retrieval cue which is phonemic in nature. At position 3, the newly established phonemic cue is relatively unique and distinct. As there are more acoustically similar items to be searched, however, this memory code becomes less unique and less distinct due either to storage deterioration (an 'acid-bath' hypothesis)⁶ or to a retrieval confusion (a 'cue-overloading' effect)⁷. Thus, in the PS condition, short processing (but long enough to have three or four items processed) has a positive effect on the item's retention. Once the phonemic code is established, however, the longer the processing time, the more items will be checked into the processor. Subsequently, prolonging the processing time has a negative effect on item's retention.

When the target word was embedded in an environment which bears no apparent relationship to the word itself, such as in the RAN and the NON conditions, the duration had no effect on the item's retention. For no matter how long the item has been held in the processor, there will be little, if any, possibility of interaction between the item and its environment.

When the item was embedded in a semantically related context, the results showed quite a different pattern. The phonemically encoded representation of the target word did not match the environmental context. In fact, the environment contained information related to the semantic rather than the phonemic aspect of the target word. The results of position 3 suggest that only two semantically related items are not enough to activate a semantic code for the target item. Thus, the SS condition functioned like the RAN and NON conditions in that recall was not facilitated by the environmental context. The results at positions 9 and 15 suggest that when the number of semantically related words searched is large enough to activate a semantic code, the recall probability is suddenly boosted and continues to grow from position 9 to 15. Thus, when the initial representation does not match its environment which contains some useful information by itself, increasing the processing time increases the possibility of discovering

that information. In these conditions, duration of processing does have a positive effect on the item's retention.

The pattern of results from the present study suggests that the effect of processing duration on item retention is a very complicated matter. An item is not processed in a vacuum; rather, the processor is always shared by other ongoing activities which become a functional environment for the processed item. To the extent that the environment does contain some information which will help the processor to establish a more durable memory code, processing time will be beneficial. When the environment contains no systematic information to help the processor to establish a unique and distinct code, time itself is not an important factor.

Relationship between reward-enhancing and stereotypical effects of psychomotor stimulant drugs

BLEULER has described stereotyped behaviour as "one of the most striking external manifestations of schizophrenia"¹. Schizophrenic stereotyped behaviour has been found in the spheres of movement, action, posture, speech, writing, thought and desire¹. Abuse of the psychomotor stimulant drugs, such as the amphetamines, methylphenidate, cocaine and pipradrol, can cause a psychosis which is clinically indistinguishable from paranoid schizophrenia², and which contains stereotyped components^{3,4}. In animals, acute doses of the stimulants can induce stereotyped behaviour which is apparently under minimal situational control, and which can disrupt normal activity⁴. In contrast, low doses of the stimulants can apparently improve learning and performance in a variety of situations, in both animals⁵ and man⁶. This paper demonstrates a relationship between these two apparently diverse actions.

The facilitation of behaviour by stimulants has been attributed to the enhancement of the effects of rewarding stimuli, by the potentiation of a brain reinforcement mechanism⁷. One of the major functions of reinforcement is to effect learning, an associative process, and it is possible for neutral stimuli, which are subsequently paired with primary rewards, such as food or water, to acquire reinforcing properties. These stimuli are termed conditioned reinforcers (CRs), and there is some evidence that stimulants can augment the effects of conditioned reinforcement^{8,9}, thus supporting the reward-enhancement hypothesis. It is, however, unclear how this hypothesis, or any other that has been advanced to explain the behavioural effects of stimulants^{10,11}, can account for the stereotyped behaviours produced by these drugs. This paper will show that stimuli with acquired motivational significance (CRs) can be crucial determinants of the selection of responses which form part of a stereotyped pattern of behaviour. Experiment 1 shows

that a dose of 10 mg kg^{-1} of the stimulant drug pipradrol, can facilitate the learning of a novel spatial discrimination task reinforced solely by a stimulus formerly correlated with reward. Experiment 2 demonstrates that although CR stimuli are important in the selection of the responses which are stimulated by pipradrol, these responses are performed in a perseverative manner, being part of a stereotyped pattern of behaviour induced by the drug.

Experiment 1 consisted of two stages. In stage 1, rats were trained either to associate, or not to associate, a specific stimulus with the presentation of water. Stage 2 tested the strength of the association formed in training, by using the stimulus as a reinforcer to sustain new learning, a stringent criterion for the establishment of conditioned reinforcement¹². Male albino rats (150–160 g at commencement of training) were provided with food *ad libitum* and subjected to a 23-h water deprivation schedule throughout the experiment. Initially, they were trained to push a panel in a standard Skinner box to collect water from an elevated dipper⁸. During stage 1, the dipper operated for 7.5-s periods, at intervals of 30 s for a total of 30 reinforcements per session, for two sessions. On three further sessions, water rewards were programmed to occur at variable intervals, averaging 30 s.

There were two conditions, CR and FS, which used different groups of rats. In the CR condition ($n=14$), a light preceded each presentation of water by 0.5 s, remaining switched on for the duration of the reinforcement. It was thus perfectly correlated with reward and was the CR stimulus. In the FS condition ($n=14$), the same light was presented according to a similar schedule, but it was randomly correlated with reward. It therefore had no associative relationship with reward and was merely a familiar stimulus (FS). There were two levers in the box during training, situated to the left or the right of, and equidistant from, the panel. Responding on either lever had no consequence for the animal in stage 1.

For stage 2, there were three 30-min sessions, each separated by 48 h to allow recovery from drug effects. No rewards of water were given during these three sessions. Animals were divided into equal drug and control groups (both $n=7$) within the CR and FS conditions. The drug groups received intraperitoneal injections of 10 mg kg^{-1} pipradrol, 15 min before each of the 30-min sessions. This dose was used since it has been found to be effective for studying the potentiation of CR by the drug in another paradigm⁹. In addition, the purpose of this experiment was to manipulate behavioural variables, while keeping pharmacological ones fixed. The control groups received injections of the drug vehicle (1:2 mixture of polyethylene glycol and distilled water). In both conditions, CR and FS, pressing one of the two levers in the box now produced the light stimulus with $P=0.5$, whereas responding on the other lever had no programmed consequence. The lever providing the stimulus was counterbalanced over subjects. This constituted a novel spatial discrimination task, reinforced solely by the light stimulus. Levers were designated as CR or NCR (no CR) or alternately as FS or NFS (no FS), in the two conditions. Responses on each lever, panel pushes and light presentations were totalled and recorded at 15 min interval during the session.

The results obtained strongly support the hypothesis that the stimulation of responding by pipradrol was controlled by the CR stimulus. An analysis of variance was carried out on the lever press totals for each rat, in the drug and control groups of the CR and FS conditions. All data were subjected to a square-root transformation to preserve homogeneity of variance¹³. The analysis revealed a significant interaction of drug with condition with the lever ($F=9.10$, d.f.=1,24; $P<0.01$), which represents the highly specific action of pipradrol illustrated in Fig. 1. Responding was greatly elevated on the CR lever in the pipradrol group,

Fig. 1 Experiment 1: Median response totals in the CR (a) and FS (b) conditions for drug and control groups, for different levers, plotted at 15- and 30-min stages for each of the three 30-min sessions in stage 2. The use of medians to express these data is preferred, because it provides a more accurate description of the group data. The use of means would greatly inflate the scores for the drug group in the CR condition due to the contributions by certain rats, of very high response totals on the CR lever. The dotted lines between sessions indicate that these are not continuous functions of time. Note the change of scale on the vertical axis, to accommodate the low response totals of the control conditions. a: Pipradrol 10 mg kg^{-1} : ●, CR; ■, NCR; Control: ○, CR; □, NCR. b: Pipradrol 10 mg kg^{-1} : ●, FS; ■, NFS; Control: ○, FS; □, NFS.

although responding on the NCR lever quickly reached control levels and lower. This shows that the stimulant action of pipradrol was restricted to the CR lever and could not therefore have been due to nonspecific increases in responding. Further, the much lower level of responding in the FS condition, for the FS stimulus, shows that the CR condition results are not simply due to the drug enhancing the reinforcing properties of stimulus change¹⁴, but depend on the learned association of the stimulus with primary reward. Pipradrol also apparently enhanced the learning of the spatial discrimination task to obtain CR. Responding for the CR initially increased over time under pipradrol, whereas responding in all other conditions generally showed monotonic decrements. In fact, all seven rats in the pipradrol group responded more for CR on session 2 than on session 1. In addition, five of these seven rats showed increases in responding on the CR lever which were concomitant with decreases in responding on the NCR lever. This pattern is consistent with the interpretation that pipradrol facilitated the learning of the task to obtain CR, and that extinction of responding only began to occur later, as the association between the CR and water became weaker. The experiment emphasises the importance of stimuli of prior motivational significance in determining the selection of responses which are stimulated by pipradrol. It also provides the most convincing evidence to date that stimulant drugs enhance the effects of conditioned reinforcement, especially since the potency of CR to sustain new learning in control organisms is not great^{12,15}, a view supported by the control data of the present experiment.

Observations of the drug-treated rats using closed circuit television revealed that these animals displayed stereotyped patterns of behaviour, which could include repetitive sniffing, head movements, rearing in the vicinity of the CR lever, and more rarely, incipient approach responses to the panel. The important question then arises: are the lever presses, in the patterns of behaviour, goal directed, occurring in spite of the competing stereotyped activity, or do they represent the perseveration of responses that were once goal directed and now form part of a stereotyped pattern of behaviour? The second possibility suggests that pipradrol

exaggerated the differences in responding on the CR and NCR levers in experiment 1, by increasing the tendency to repeat responses. It also suggests that stereotyped behaviour can have learned components.

Experiment 2 tests between these hypotheses by using a task in stage 2 in which perseveration of responding acts against, rather than in favour of, learning. If it is possible to demonstrate that the lever pressing for CR has perseverative properties, then its similarity to other forms of stereotyped activity would be underlined. Stage 1 was similar to that of experiment 1, except that the CR stimulus was 0.5 s long. In stage 2, the CR consisted of this stimulus and the brief (0.3 s) elevation of the empty water dipper. To obtain CR, the learning of a two-component response sequence was required, involving a single response on each lever, made in the precise sequence, component 1, component 2. Thus perseveration of responding on either lever would lead to disruption of learning and a reduction in obtained CRs.

Rats trained as previously were injected with either 10 mg kg⁻¹ pipradrol ($n=6$), or vehicle ($n=6$), 15 min before each of six 30-min sessions. Figure 2 shows that there was a remarkably similar pattern of responding to that shown in experiment 1. There were sharp increases in responding on the second component of the response sequence, concomitant with decreases in responding on the first component, for drug-treated rats. This perseveration of responding led to a progressive reduction in obtained CRs, although the absolute response rate was still increasing.

Fig. 2 Experiment 2: Median response totals plotted over the six 30-min sessions of stage 2 for component 1 and component 2 lever press totals. The differential stimulation of component 2 over component 1 in the drug group, as compared with the control group, is significant, following an analysis of variance similar to that used in experiment 1 ($F=6.43$, d.f.=1,10, $P<0.05$). Note the change of scale on the left-hand side vertical axis. Median CR totals are also plotted on the right-hand side vertical axis, as a function of sessions. Pipradrol 10 mg kg⁻¹: ●, component 2; ○, component 1; ▲, reinforcement; control: ■, component 2; □, component 1; △, reinforcement.

There were, in fact, no overall differences in the number of CRs obtained by the drug and control groups (Mann-Whitney U test, $P=0.132$, two-tailed). It is of great importance that the stimulation of responding in the pipradrol group always occurred for the component of the sequence closest in time to the presentation of CR. Although the selection of the response was once again controlled by the CR contingency, however, its performance was perseverative, since it resulted in a reduction of obtained CRs.

Pipradrol thus clearly failed to sustain the learning of the response sequence to obtain CR. The fact that responding was perseverative, and integrated into a stereotyped pattern of behaviour, as in experiment 1, shows, however, that it is probable that stereotyped behaviour can have learned components. It is of course difficult to say whether most forms of stereotypy result from the perseveration of responses formerly goal directed. It is clear that the learned components in the present patterns were not performed indefinitely; extinction of them occurred in most instances, showing that perseveration does not completely override environmental controls. It is interesting, however, that responding was very persistent in certain cases in experiment 2, in which the frequency of CR was low, therefore diminishing the opportunity for extinction of the original association of the CR with water. One rat showed increasing response rates over the six sessions, making more than 3,400 responses on the last session, receiving only one CR. The results from both experiments support the hypothesis that a general action of stimulant drugs is to cause increased repetition of responding, with response selection being dependent in part on environmental contingencies³. Thus the 'reward-enhancing' and stereotyped effects of the psychomotor stimulants are postulated to arise from the action of a common mechanism.

This hypothesis can explain the apparent conditioning of stereotypy in amphetamine-treated cats, as well as the subsequent 'fragmentation' and ritualisation of their responses into stereotyped patterns¹⁶. It can also explain the idiosyncratic nature of the stereotypies of human amphetamine addicts, which involve perseveration of well-established habits such as car maintenance and house cleaning³. Finally, it has implications for the apparently meaningless stereotyped activities of certain psychotic states, such as autism¹⁷ and schizophrenia^{1,2,18}. It is suggested that these activities may arise from a fixation on behaviour which had been initially purposeful. In support of this, Bleuler¹ has described schizophrenic stereotypies which were related to events of significance occurring in the previous history of the subjects. This paper has shown that an analogous mode of behaviour may occur in rats treated with amphetamine-like drugs, and strengthens the use of drug-induced behaviour as model psychoses.

I thank Drs S. Iversen, G. Koob, M. Morgan, B. Sahakian and P. Fray for discussions, Ms C. Andrews for assistance, Merrell and Co. for pipradrol and Professor O. L. Zangwill for research facilities.

Influence of ethylene and oxygen on respiration and peroxide formation in potato tubers

APPLICATION of ethylene to potato tubers induces a respiratory upsurge¹, comparable with that in ripening climacteric fruit², but which can be studied independently of other ethylene-induced processes occurring in fruit. It has been suggested that ethylene catalyses oxygen-requiring processes, reflecting in part oxygen utilisation in the formation of peroxides³. We report here that high O₂ tensions, in combination with ethylene, markedly enhance the respiratory rise, which is accompanied by a corresponding increase in peroxides.

Locally grown potato tubers (*Solanum tuberosum* L., variety Northchip) were preconditioned at room temperature for 2 weeks after harvest. Four tubers weighing together approximately 1.0 kg were each placed in a 4-l jar and ventilated continuously, at a flow rate of 400 ml min⁻¹, with 21% (air) or 100% O₂, supplemented with 0 or 10 p.p.m. ethylene as previously described³. The potatoes were kept at 21 °C throughout the experiment. Evolution of CO₂⁴ and peroxide⁵ was monitored at 6-h intervals for 36 h. All determinations were run in duplicate.

Figure 1a and b shows that in the absence of ethylene respiration was at a steady rate in both air and 100% O₂, although in oxygen the rate was somewhat higher. Addition of ethylene to air resulted, after a lag, in a respiratory rise, reaching a peak two or three times the initial rate after

Fig. 1 Effect of ethylene on CO₂ evolution (a and b) and peroxide formation (c and d) in air (21% O₂) and 100% O₂. Ethylene concentrations were zero (○) and 10 p.p.m. (●).

24 h, followed by a decline. By comparison, after a comparable lag, ethylene in 100% O₂ induced a rapid rise in respiration to almost ten times the initial rate.

The results show that although ethylene was required to trigger the respiratory rise, as previously observed¹, oxygen tension was the rate limiting factor. A similar interaction between oxygen and ethylene has been obtained in the induction of synthesis of lycopene, the red tomato pigment, in the non-ripening *rin* mutant³. As in potato respiration, ethylene was obligatory for the initiation of lycopene synthesis but O₂ tension was the rate limiting factor.

We hypothesised that the changes in the oxygen tension reflect, in part, peroxide formation and that ethylene triggers the process, because (1) ethylene stimulated peroxide formation in fruit⁶, and (2) peroxide forming enzymes are stimulated by high O₂ tensions⁸.

To test this hypothesis, we measured the changes in peroxides in the tubers as related to the effect of different O₂ tensions with and without ethylene. As with CO₂ evolution in the absence of ethylene, the peroxide level did not change in air or 100% O₂ (Fig. 1c and d, respectively). Addition of ethylene resulted in an upsurge in the formation of peroxides. As with CO₂ evolution, the peroxide levels were stimulated by high O₂ tensions.

Solomos and Laties⁷ proposed that ethylene triggers an alternative respiratory pathway (cyanide insensitive). Our demonstration that the respiratory rise, as influenced by ethylene and oxygen, is accompanied by an upsurge in peroxides suggests that the alternative respiratory pathway leads to the formation of peroxides.

The formation of peroxides in plants is catalysed by several enzyme systems⁸, but may also result from the dismutation of superoxides⁹. In any case, the upsurge in peroxides represents the formation of partially reduced oxygen forms, while in respiration molecular oxygen is reduced completely (formation of water). The action of ethylene, as shown in potatoes, may therefore be to divert the flow of electrons from the complete reduction of molecular oxygen to the formation of partially reduced oxygen forms, such as peroxides, which by comparison with O₂, represent oxygen forms which readily react with cellular constituents^{8,9}. In this way, ethylene may induce redox changes in tissues, including the oxidative breakdown of senescence-retarding hormones in fruits⁹, and thereby the onset of senescence processes.

Characterisation of human cell lines and differentiation from HeLa by enzyme typing

THE value of a great deal of research on cells in culture depends on the certain identity of the cells under investigation. Contamination of one cell line with another, leading to mixed cultures or in some cases complete overgrowth of the original cells by the contaminating line, is a long-standing problem. Interspecific contamination has been

recognised by both immunological and karyological techniques^{1,2}, but the most striking demonstration of intra-specific contamination was by Gartler³. He presented evidence, based on the detection of common genetically determined variation in two enzymes, that many permanent tumour cell lines, set up originally in several different laboratories, were in fact HeLa cells. Recently the problem of contamination with HeLa has become a focus of general interest and there has been a search for certain chromosomal and other characteristics of HeLa in a large number of established lines⁴⁻⁶. There is no guarantee, however, that the contaminating cell line will always be HeLa and there appears to be a need for a quick and reliable method for the absolute identification of all human cell lines.

In recent years more has become known about genetic diversity in man, and many electrophoretically distinguishable enzyme polymorphisms have been discovered⁷. Most of this information has come from studies on red cells and placenta, but many polymorphic loci are expressed in cultured cells. Thus it is already possible to devise a relatively simple scheme which goes a considerable way towards the positive identification of individual human cell lines. As new polymorphisms are discovered it will doubtless be improved. We present here our current list of enzyme polymorphisms which we have found useful for the identification of all types of cultured cells, including diploid and transformed fibroblasts and permanent lymphoblastoid lines. We have been able to test out the scheme

*PGM*₁, *PGM*₂, *PGM*₃: first, second and third loci of phosphoglucosmutase. *GOT*_M: mitochondrial glutamate-oxaloacetate transaminase. *ESD*: esterase D. *AK*₁: adenylate kinase. *ADA*: adenosine deaminase. *ACP*₁: 'red cell' acid phosphatase. *PGD*: phosphogluconate dehydrogenase. *G6PD*: glucose-6-phosphate dehydrogenase. *PEP A* and *PEP C*: peptidases A and C. *ACON*_s: soluble aconitase. Enzymes bracketed together were routinely run on the same gel. Electrophoresis and detection of enzymes were by methods previously described⁷.

*The phenotype frequencies of many of the enzymes show marked regional variations even within the same ethnic group. The most reliable data are from the North European population surveys. Wherever possible the phenotype frequencies given for the Black population are derived from population studies on Yorubas from Nigeria.

†Enzyme not found in red cells.

‡The *G6PD* A phenotype includes both A(-) and A(+), since these are difficult to distinguish in cultured cells. The frequency of the A and B phenotypes is very variable in different populations and this estimate is from Nigerian males. We have used the male frequencies to calculate the chance of two cell lines being alike since a line in long-term culture might be expected to be effectively monoclonal and thus to express only 1 allele at an X-linked locus such as *G6PD*.

§The frequencies given for *PEP A* ignore the *PEP A*⁺ allele which is technically difficult to distinguish from *PEP A*¹.

¶Some alleles at the *PEP C* locus are not expressed in red cells and reliable population data are not available for the Black population (see refs 7 and 11).

on five permanent epithelial cell lines derived from human bladder tumours. These results are presented together with findings on nine other permanent human cell lines, all of which seem to be, or are known to be, HeLa.

Details of the enzymes used in our cell identification scheme are given in Table 1. The loci selected are in general those which have useful gene frequencies in different populations, and which have been studied in detail in both cultured cells and in families. All the loci are expressed in other tissues, and ten of them are expressed in red cells (Table 1) so that the best positive check on the identity of a cell line can be made if blood or other tissue is set aside for enzyme testing when the cells are put into culture. Using starch gel electrophoresis it is not necessary to run a separate gel for each enzyme. As Table 1 shows, the seven enzymes providing the most information (the first seven tested, excluding PGM₂) are usually run on only three gels, and could be done on fewer if necessary. Using routine methods the enzymes suggested could all be done on a single pellet of 10⁷ cells.

Three of the enzymes listed in Table 1 require further comment. Adenosine deaminase (ADA) and occasionally acid phosphatase (ACP₁) may be difficult to type in diploid fibroblasts, because of a preponderance of 'tissue' isozymes in which genetic variation is not detectable. The adenylate kinase locus (AK₁) is not expressed in lymphoid lines. In our experience all the loci listed in Table 1 are readily typeable in permanent epithelial lines.

Table 1 also shows the chance of being able to distinguish any two individuals, of similar racial origin, using these enzyme loci; this turns out to be about 97% in North Europeans and about 99% in Blacks. The chance of distinguishing any two lines of dissimilar racial origin would of course be greater. Further information may be obtained by testing other enzymes which have been omitted from this scheme because variants occur only at low frequencies. Some cell lines would be found to be heterozygous for one of these variants if sufficient loci were tested¹². There are also several fairly recently discovered enzyme polymorphisms that have not yet become established in our laboratory as routine markers for cultured cells, but which will probably be useful in the future. These include mitochondrial malic enzyme^{13,14}, glyoxalase I¹⁵ and uridine monophosphate kinase¹⁶. α -Fucosidase may also be included in the scheme, but it requires an additional technique, isoelectric focusing^{17,18}.

The results of testing a series of human cell lines by the scheme outlined above are given in Table 2. Five lines were derived from bladder tumours and maintained at the

Imperial Cancer Research Fund Laboratories. All these were of North European origin: RT4 was an English male¹⁹; RT112 an English female (C. C. Rigby and L.M.F., unpublished observations); T24 was a Swedish female²⁰; J82 was a Swedish male (provided by Carol O'Toole, University of California) and EJ was an American male (provided by J. Daly, Massachusetts General Hospital). Most of the other lines are well known strains of HeLa and all except BU25 (ref. 21) have featured in a recent investigation of cell identity⁵. The two remaining lines, LU and EUE, were originally set up as independent lines from foetal lung and subcutaneous foetal tissue respectively^{22,23}. They were sent to us for typing because they were suspected of having been taken over by HeLa and in fact the enzyme types were found to be those characteristic of HeLa cell lines. All the cells tested were sent to the Galton Laboratory in the form of washed cell pellets.

Clearly the bladder tumour lines are not the same as HeLa and differ among themselves. Three of them have unique enzyme phenotypes. The other two, J82 and EJ, are the same as each other on the enzymes tested in Table 1 and so appear to be identical. This is unfortunate but statistically not too distressing since if the chance of any two individuals being the same is 3%, the chance of finding two alike in a sample of five lines is about 1 in 4. Thus the evidence at present is not strong enough to suggest that one line has been taken over by the other, but clearly this is a possibility. Attempts to distinguish the two lines using other enzymes including α -fucosidase and glyoxalase I have so far been unsuccessful. They both seem to be phenotype α FUC 2-1 and GLO 1. The chance of two lines from different individuals being identical for these two enzymes is about 1 in 4. The two lines do, however, differ in other properties (C. J. Marshall, L.M.F. and A. W. Carbonell, in preparation). EJ cells produce tumours in nude mice and have a colony-forming efficiency in agar of 23%. J82 cells do not form tumours in nude mice in our experiments and have a colony-forming efficiency in agar of 3%. The problem of identification encountered here illustrates the usefulness of directly testing material such as red cells, white cells, or in these cases samples of the tumours from the original donors.

The reliability of enzymes as genetic markers for cell identification depends on the stability of the enzyme phenotypes in culture. We have attempted to check this particular point by repeatedly testing cells in culture over various periods of time. Whenever possible, material from the original donor has also been examined. We have monitored more than 100 lymphoid lines from more than

In addition to the enzymes shown here D98 was tested for lactate dehydrogenase (LDH_A and LDH_B), mannose phosphate isomerase (MPI), superoxide dismutase (SOD_A), soluble and mitochondrial malate dehydrogenase (MDH_s and MDH_M), isocitrate dehydrogenase (ICD_s), purine nucleoside phosphorylase (NP), glucose-phosphate isomerase (GPI), adenine phosphoribosyl transferase (APRT), enolase (ENO₁), glyoxalase I (GLO) and mitochondrial malic enzyme (ME_M). It seemed to have the common homozygous phenotype at all these loci with the exception of ME_M, for which no satisfactory result was obtained. However, two other HeLa strains tested for ME_M (HELA_{s3} and LU) were clearly heterozygotes, phenotype ME_M 2-1.

70 people, about 100 primary fibroblast cultures and a small number of permanent epithelial lines in addition to those described here. From one lymphoid line more than 500 clones were examined, each for an average of 30 loci, 300 of these clones having been treated with large doses of mutagen (ref. 24 and further unpublished data). The total number of tests performed has been more than 20,000, since many lines have been checked repeatedly. In all these cells only two examples of a true mutation, involving alteration of electrophoretic mobility, have been seen (ref. 23 and unpublished work). Loss of enzyme activity, often involving only one allele so that an apparent homozygote is produced, has also been observed but with very low frequency²⁴. In several of these cases this was associated with a specific chromosomal aberration²⁵. On 15 other occasions an apparent change in phenotype was observed, three times in fibroblast cultures and 12 times in lymphoid lines. These changes were conclusively shown to be due to contamination by checking other enzymes and by karyotype analysis.

Clearly more extensive investigations into the identity of cell lines would be desirable, and other workers have suggested HLA typing²⁶ and monitoring of the karyotype, particularly for the presence or absence of a Y chromosome⁶. Both of these methods have many advantages which we do not wish to ignore. We feel, however, that the routine testing of enzyme phenotypes, while perhaps not yet equalling the theoretical discriminating power of the HLA system, is such a reliable and simple tool for the characterisation of human cultured cells that it should be adopted with much greater enthusiasm than hitherto.

We thank everybody who provided cells, in particular Mrs Valerie Hemmings, Imperial Cancer Research Fund Laboratories, Dr E. Arthur and coworkers and Mr W. Christie, MRC Clinical and Population Cytogenetics Unit, and Drs Ian Craig and Bengt Bengtsson, Genetics Laboratory, University of Oxford. We also thank Drs Carol O'Toole and J. Daly for the initial cultures of J82 and EJ cells, respectively, and colleagues in the Galton Laboratory, especially Drs J. Delhanty and J. Parrington, for their help.

Phenotypic reversion of ricin-resistant hamster fibroblasts to a sensitive state after coating with glycolipid receptors

THE cytotoxicity of the plant lectin ricin, of *Ricinus communis* seeds, towards mammalian cells is mediated in three steps¹. Binding of the toxin to cell surface galactose or *N*-acetylgalactosamine receptors is followed by entry of the bound lectin into the cells, perhaps by endocytosis^{2,3} and inhibition of protein synthesis⁴⁻⁶. Several variant lines of cells selected for resistance to ricin have been shown⁷⁻¹⁰ to bind ricin poorly and to carry much smaller amounts of receptors at the cell surface. We report here that when such a resistant cell line of baby hamster kidney (BHK) fibroblasts^{8,9} is incubated with a ricin-binding glycolipid fraction prepared from human erythrocytes, glycolipid is taken up and the cells exhibit increased binding of ricin and greater sensitivity to lectin-mediated inhibition of cell protein synthesis. These studies suggest that glycolipids can function in certain circumstances as membrane receptors in the binding of ricin and mediation of ricin cytotoxicity.

Baby hamster kidney (BHK) cells and the ricin-resistant variant, Ric^R21 were grown at 39 °C in Glasgow modified Eagle's medium (GMEM) supplemented with 10% tryptose phosphate and 10% foetal bovine serum as described previously^{8,9}.

A ricin-binding glycolipid fraction was isolated from human blood group O erythrocytes as described before¹¹⁻¹³. The fraction soluble in chloroform:methanol:water (1:2:1) containing fucose (8%), galactose (41%), glucosamine (33%), fatty acids (4%) and sphingosine (5%) was evaporated to dryness just before use, dissolved in water at 5 mg per ml and the resulting transparent aqueous solution was sterilised by filtration. ¹⁴C-labelled glycolipid was prepared by de-*N*-acetylation in *N*-sodium hydroxide at 100 °C for 30 min and reacylation with ¹⁴C-acetic anhydride after neutralisation and dialysis. The specific activity was 1.3×10^6 c.p.m. mg⁻¹.

As Fig. 1 shows, when cells were incubated in phosphate-buffered saline (PBS) with ¹⁴C-labelled glycolipid about 2% of the labelled glycolipid was taken up in cell-bound form regardless of the initial concentration of glycolipid added. Maximum uptake by cells required 4 h of incubation with the glycolipid fraction at 39 °C. Measurable binding did not occur at 2 °C. Cells incubated for 4 h at 39 °C with glycolipid ($50 \mu\text{g ml}^{-1}$) incorporated, in several independent experiments, $5-12 \times 10^6$ molecules per cell. At this time no radioactivity was released from the cells by brief trypsinisation ($2 \mu\text{g ml}^{-1}$ at 39 °C for 5-15 min) indicating that the cell-bound glycolipids were not loosely attached, for example, to serum proteins adsorbed at the cell surface.

Incorporated glycolipid increased the binding of radioiodinated ricin to normal BHK cells as well as to the ricin-resistant variant, Ric^R21 (Fig. 2). With cells containing 5×10^6 molecules of glycolipid per cell, ricin binding was enhanced to a similar extent by approximately 3×10^6 sites per cell. The enhancement was most marked with Ric^R21 cells which by themselves show only about 10% of the ricin-binding capacity of normal BHK cells (Fig. 2). After glycolipid treatment ($50 \mu\text{g ml}^{-1}$) ricin binding was increased threefold. The enhancement of ricin binding was

Fig. 1 Binding of ^{14}C -labelled human erythrocyte glycolipids to BHK cells. Confluent monolayers of parental BHK cells (●) or ricin-resistant variant (○), Ric^R21, on 35-mm diameter plastic dishes (4×10^6 cells per dish) were exposed in 1 ml of PBS to various concentrations of the ^{14}C -labelled glycolipid fraction at 39 °C for 4 h. The saline was removed, the cells were washed three times with saline and then solubilised in 1 ml of N-NaOH and counted for bound radioactivity. Other portions were assayed for protein.

greater, about sixfold, after treatment of Ric^R21 cells with glycolipid at $500 \mu\text{g ml}^{-1}$, and ricin binding then approximated to that of normal BHK cells. Ricin binding to normal BHK cells was doubled after similar treatment. But the enhancement of ricin binding, $6-7 \times 10^6$ sites per cell, was considerably less than the numbers of glycolipid molecules bound to the cells after treatment with $500 \mu\text{g}$ of glycolipid. We conclude that cells exposed to very high concentrations of glycolipids ($500 \mu\text{g ml}^{-1}$) take up glycolipids either intracellularly or in surface sites that are not accessible to ricin added externally. Perhaps in these conditions glycolipids in part were sequestered intracellularly by pinocytosis. We do know, however, that the glycolipids used in this work can be incorporated into erythrocytes in which pinocytosis is improbable, and confer Lewis and ABO-blood group activity on these cells¹³.

Whatever the mechanism of incorporation¹³, treatment of BHK cells with glycolipids, in conditions in which an association with the cell surface could be demonstrated by an enhancement of ricin binding, was found to increase the sensitivity of the cells to ricin. Ricin-mediated inhibition of cell protein synthesis was measured as follows. Confluent monolayers of normal BHK cells or ricin resistant Ric^R21 variant cells growing on 35-mm diameter plastic dishes were incubated in GMEM minus serum (1 ml) with ricin ($1 \mu\text{g}$ or $10 \mu\text{g}$). After 1 h at 39 °C, 1 ml of ^3H -leucine ($3.3 \mu\text{Ci}$, 59 Ci mmol^{-1}) in leucine-free GMEM was added to each dish. Incorporation was carried out over 1-6 h when the medium was removed and the cell monolayers were washed three times with PBS, twice with cold (2 °C) 2% phosphotungstic acid-10% perchloric acid and twice with cold alcohol. The washed monolayers were then dissolved in hot (80 °C) N-NaOH

Table 1 Inhibition of BHK cell protein synthesis by ricin

Cells were incubated for 4 h at 39 °C with or without erythrocyte glycolipid fraction as indicated. The cells were then washed and incubated with ricin ($1 \mu\text{g ml}^{-1}$ or $10 \mu\text{g ml}^{-1}$) for 1 h at 39 °C before assay of ^3H -leucine incorporation into cellular protein. Control dishes contained no ricin and showed that treatment of cells with glycolipid had no effect on the level of ^3H -leucine incorporation into protein.

*This solution was supplemented with 10 mM lactose.

†A degraded glycolipid derivative which shows no ricin-binding activity was prepared¹³ by Smith oxidation with 40 mM sodium periodate in 50 mM sodium acetate buffer, pH 4.5 overnight at 4 °C to destroy galactose terminal units. Excess oxidant was destroyed with ethylene glycol and dialdehydes were reduced with sodium borohydride at room temperature for 1 h. Excess borohydride was destroyed by acetic acid and acetal linkages were hydrolysed in 0.5 N HCl at 20 °C for 8 h. Finally the degraded glycolipid fraction was dialysed extensively against water and freeze dried. The material was then dissolved (5 mg ml^{-1}) in water.

Fig. 2 Binding of ^{125}I -ricin to BHK cells before and after treatment with erythrocyte glycolipids. Normal cells (a) and ricin-resistant variant Ric^{R21} (b) were grown to confluency on 35-mm diameter plastic dishes (4×10^6 cells per dish). Growth medium was removed and duplicate monolayer cultures were incubated at 39 °C with 50 µg or 500 µg of glycolipid in 1 ml of PBS. Control dishes were incubated with PBS. At various times, unbound glycolipid was removed by washing three times with saline and ^{125}I -ricin (50 µg, 3.5×10^5 c.p.m.) in PBS (1 ml) added at 2 °C. After incubation of control cells and glycolipid-treated cells with ricin for 60 min at 2 °C the monolayers were washed three times with saline, dissolved in 1 ml N-NaOH and counted. Ricin binding is expressed in terms of cellular protein and corrected for non-specific binding of ^{125}I -ricin to cells (control or glycolipid-treated) in the presence of hapten inhibitor (10 mM lactose) and to dishes containing no cells to which appropriate amounts of glycolipid had been added, incubated at 39 °C for the stated times and then washed with saline. In no case did the nonspecific binding (lactose irreversible counts or counts bound to dishes) exceed 20% of the radioactivity bound in the absence of lactose to cell layers in identical conditions. ● and ○, 500 µg glycolipids; ■ and □, 50 µg glycolipids; ▲ and △, controls.

(1 ml) and portions (0.2 ml) were removed for radioactive counting and protein assays. Incorporation of ^3H -leucine into protein by normal BHK cells was inhibited about 80%, by ricin at $1 \mu\text{g ml}^{-1}$ and 90% by ricin at $10 \mu\text{g ml}^{-1}$ (Table 1, experiment 1). In contrast, protein synthesis of the resistant variant, Ric^{R21}, was unaffected by these concentrations of ricin (Table 1, experiment 1). As Table 1 shows, in Ric^{R21} cells incubated with glycolipids for 4 h at 39 °C and then, after washing, with ricin ($1 \mu\text{g}$ or $10 \mu\text{g}$) for 1 h, the incorporation of ^3H -leucine into protein was decreased significantly compared with cells not pretreated with glycolipids. The already high sensitivity of normal BHK cells to these concentrations of ricin also appeared to be significantly increased by pretreating cells with glycolipids (Table 1, experiment 1). The magnitude of the effect of Ric^{R21} cells was dependent on glycolipid concentration to some extent (Table 1, experiment 2). Furthermore, the effect of ricin on Ric^{R21} cells pretreated with glycolipids was abolished by inclusion

of 10 mM lactose in the culture medium (Table 1, experiment 2). Additional evidence that the potentiation of ricin cytotoxicity by pretreatment of Ric^{R21} cells with glycolipids requires binding of lectin to the carbohydrate moiety of the glycolipids was obtained using a degraded glycolipid fraction (Table 1, experiment 3). Oxidation of the glycolipid fraction with periodate destroys preferentially the ricin-binding terminal galactose residues of the molecule¹³. When this material was incorporated into Ric^{R21} cells, there was no change in the high resistance of the cells to ricin (Table 1, experiment 3).

We conclude from our results that a ricin-binding glycolipid fraction extracted from human erythrocytes when added to baby hamster kidney fibroblasts becomes tightly associated with the cells. Such incorporation increases the numbers of toxin molecules that can bind to the cells and the cells concurrently become considerably more sensitive to the cytotoxic action of ricin as indicated by a decreased incorporation of ^3H -leucine into cellular proteins. It is unlikely that complex glycolipids containing twenty or more monosaccharides and conferring blood group specificity on human erythrocytes exist endogenously in hamster fibroblasts. But other ricin-binding glycolipids, for example ganglioside GM1 (ref. 14), are known that could function as the normal receptors mediating ricin toxicity in sensitive BHK cells. Preliminary evidence shows no detectable levels of GM1 or GM2 in either normal BHK cells or Ric^{R21} cells, however, and the levels of other galactolipids, GM3 (hematoside) and lactosylceramide, are similar in the two cell lines. We therefore favour the alternative interpretation that incorporation of relatively large amounts of "foreign" glycolipids into the BHK surface membrane can mimic the normal route, for example through glycoprotein receptors, by which the toxin enters these cells.

It is clear that the incorporated glycolipids are less efficient in mediating ricin toxicity than are the natural receptors. Thus, Ric^{R21} cells that bound sufficient glycolipid to enhance ricin binding to approximately the level exhibited by normal BHK cells (6×10^6 sites per cell) were only about half as sensitive to ricin (Table 1, experiment 1). The mechanism by which glycolipid incorporated into the surface membrane participates in ricin cytotoxicity is, of course, unknown. It may do so directly, or by association with integral glycoproteins, perhaps those that in normal cells carry the ricin-binding sites. We have no unequivocal way of deciding between these two mechanisms, neither of which would be expected to be as efficient as the normal process. In the latter case, it may be that the association of glycolipid with putative glycoprotein mediators of ricin toxicity involves only a small proportion of the total glycolipid incorporated into the cell membrane. Perhaps only when the membrane is heavily loaded with glycolipid does the number of glycoprotein molecules "primed" with glycolipid receptors reach a threshold value necessary for permeation of ricin into the cells.

Cellular adhesiveness reduced in ricin-resistant hamster fibroblasts

THE means by which tissue cells adhere to one another and to non-cellular surfaces is not known, although complex carbohydrate of their surface membrane may be involved^{1,2}. To test this, one can ask whether mutations which affect

the structure of surface carbohydrate also alter cellular adhesiveness. Meager *et al.*³ have isolated a series of stable variants of baby hamster kidney fibroblasts (BHK 21, clone 13) which are resistant to the toxic lectin ricin. The first step in killing of cells by ricin is binding of the lectin to galactosyl- or *N*-acetylgalactosaminyl residues at the cell surface^{4,5}, and many ricin-resistant clones yield cell lines with reduced glycosylation of their cell surfaces³. We now report that, judged by their ability to form aggregates in suspension, the intercellular adhesiveness of a number of ricin-resistant lines is less than unselected lines. We have also found that cells of most lines attach less readily than controls to glass coverslips bearing adsorbed films of serum or gelatin.

After 24 h of incubation in a gyratory shaker⁶, suspensions of control cells yield compact spherical aggregates approximately 200 μ m in diameter (Fig. 1). Ricin-resistant

Fig. 1 Darkground micrographs of aggregated suspensions of BHK 21 cells and ricin-resistant derivatives after gyratory shaking for 24 h. *a*, C13 cells from which ricin-resistant cells were selected. *b*, Mutagenised but unselected control (see below) and resistant lines as numbered. Confluent cultures grown in Glasgow-modified Eagle's medium supplemented with 10% foetal bovine serum and 10% tryptose phosphate (EFT) were dispersed using EDTA and trypsin¹⁷. Cells were resuspended in EFT at 5.10^6 per ml. 2 ml of each suspension was cultured in a 25-ml silicone-treated conical flask, with gas phase air, 95%, CO_2 5%, in a gyratory shaker⁶ at 70 r.p.m. 37 °C for 24 h. 0.25-ml samples were photographed in a dish, diameter 14 mm. C13 cells from which ricin-resistant cells were selected at Mill Hill (*a*) in Figs 1-3) showed adhesive properties very similar to Glasgow stocks used in earlier experiments^{8,17}. Two further control lines were obtained by mutagenising C13 cells as for selection, but then growing out the subclones in the absence of ricin. Our unpublished experiments show that cells of lines Ric¹⁴, 19 and 21, but not 22, have lost the ability to readhere in the early phase of aggregation which occurs in the first hour of shaking of freshly suspended cells¹⁷. This assay is not satisfactory for comparing lines selected from C13 cells, because it is relatively easy to obtain from C13 stocks without selection, lines which do not aggregate in the first hour from trypsin dispersal¹⁸. Lines of this phenotype do however aggregate very similarly to unrecycled C13 cells when cultured for 24 h in a gyratory shaker.

(Ric^R) lines exhibit a range of reduced aggregation behaviour, from Ric^R22 which differs from controls only in forming smaller aggregates, to Ric^R7 and 17 which aggregate very little. Quantitation by use of a Coulter counter shows that these comparisons are repeatable and stable through a month's consecutive passage of the cells (Fig. 2) and after storage of cells in liquid nitrogen for 1 yr. Figure 3a shows that freshly dispersed cells of Ric^R19 and 22 adhere to a film of adsorbed foetal bovine serum to the same extent as controls, whereas the remaining six tested adhere less well. This behaviour is not specific to foetal calf serum, for the pattern is similar with calf serum and gelatin (Fig. 3b), although there is much more day to day variation on these latter films.

Ric^R22 cells exhibit at confluence the parallel alignment characteristic of the parental cells, bind normal levels of ricin^{3,7} and as shown here, also resemble wild type in adhesive behaviour. This agrees well with the evidence that the moderate resistance to ricin of this line depends on a cytoplasmic, rather than a surface alteration⁷. Ric^R12, 16 and 19 are lines which do not show a reduction in ricin binding, but nevertheless may have reduced surface glycosylation, since they are cross resistant to the lectin from *Phaseolus vulgaris*³. The remaining lines, including those

Fig. 2 Aggregation of suspensions of BHK 21 cells and ricin-resistant derivatives measured using an electronic particle counter. *a*, C13 cells from which ricin-resistant cells were selected; *b* and *c*, mutagenised but unselected lines; *d*, Glasgow stocks of C13 cells. 0.1-ml samples of suspensions aggregated as for Fig. 1 were diluted in 20 ml of 0.9% w/v sodium chloride and counted in a Coulter counter Z_B, using a 200-μm aperture⁴. Data are the concentration at 24 h of particles of all sizes divided by the value before incubation. For each cell line, means and standard deviations are shown from six to eight separate experiments, spread through about eight consecutive passages of the cells. The count does not reflect the tendency of Ric^R22 to form smaller aggregates than wild-type cells since the assay is dominated by the proportion of particles representing single cells and very small clusters. Values greater than 1 for Ric^R17 indicate limited cell division in the cultures.

most conspicuously affected in aggregation (7 and 17) all bind only 10–40% as much ricin as do wild type³. The aggregation properties of these lines are therefore broadly consistent with the proposal that intercellular adhesion requires carbohydrate chains which are potential acceptors of terminal sialyl residues^{8–10}. Indeed this 'sialyl acceptor' model predicts a strong correlation between ricin resistance and decreased intercellular adhesiveness, for those monosaccharide residues often terminal in sialic-acid free carbohydrate chains (galactose or *N*-acetylgalactosamine), are the same as those required for ricin binding. Besides these residues, the model requires the existence of a cell-surface protein with carbohydrate-binding activity (perhaps a sialyl transferase³ or lectin-like protein¹¹) of specificity resembling

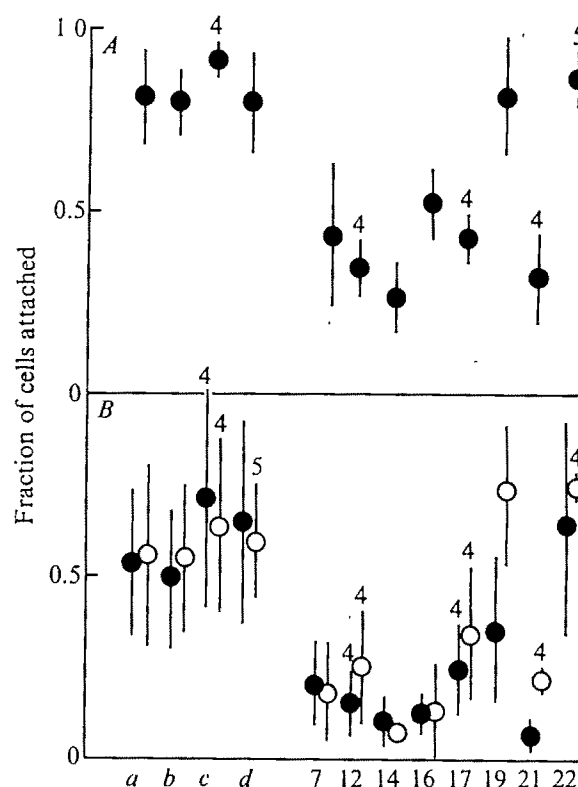

Fig. 3 Attachment of BHK 21 cells and ricin-resistant derivatives to glass coverslips bearing adsorbed protein films. *A*, foetal bovine serum; *B*, calf serum (solid symbols) gelatin (open symbols). *a–d* as Fig. 2. Data are the fraction of cells which had attached after 45 min. Mean and standard deviation of 4–14 experiments on each line, number shown where less than six. Attachment was measured much as described by Rabinovitch and De Stefano¹⁹ except that cells were labelled by incorporation of ³²P-phosphate. Cells were grown for 24 h in medium minus tryptose phosphate (EF) containing 2 μCi of ³²P-phosphate per ml, which was then replaced with unlabelled EFT for a further 18 h growth. Cells dispersed with EDTA and trypsin were re-suspended in Hanks medium, pH 7.2, buffered with 0.01 M HEPES medium at 10⁶ cells per ml. Protein-coated coverslips¹⁸, diameter 13 mm, were drained but not allowed to dry, immediately before receiving 0.1 ml of cell suspension. After incubation for 45 min in a humid atmosphere at 37°C, the coverslips were rinsed in Hanks-HEPES, drained and transferred directly to scintillation phials for counting without further processing. Data are c.p.m. retained as a fraction of total c.p.m. in 0.1 ml cell of suspension, from triplicate coverslips in each experiment.

ricin. We have found that homogenates of BHK cells contain a haemagglutinin selectively inhibited by *N*-acetylgalactosamine and D-fucose¹², but we do not yet know if it is involved in the adhesive phenomena described here. The sialyl-acceptor model does not readily explain the simultaneous effect of the mutations in most lines on both intercellular adhesion and adhesion to substratum. Possibly carbohydrate binding is involved in some purely *cis* interaction (such as clustering in the plane of the surface of a glycoprotein involved in adhesion) rather than, or in addition to, a *trans* role (Fig. 4). Alternatively, one of the interacting components could simply adsorb to the substratum¹². We should stress, however, that there is no direct evidence that protein-carbohydrate 'recognition' is involved in any adhesive properties of these cells. Indeed interpretation of the adhesive changes as a direct result of decreased cell-surface glycosylation may yet prove to be an oversimplification to, a *trans* role (Fig. 4). Alternatively, one of the inter-resistant BHK cell lines lacks a glycoprotein of approximate molecular weight 250,000 which can be labelled by lactoperoxidase-catalysed iodination¹⁴, and such surface components may themselves be involved in cell adhesion^{13,15}.

Fig. 4 Possible roles for carbohydrate-protein binding in cell adhesion. *a*, Sialyl-acceptor model⁸, in which an oligosaccharide (solid hexagons) of cell-surface carbohydrate, with terminal galactose or *N*-acetylgalactosamine is bound by a specific receptor on a second cell. *b*, Alternative interaction in which a similar receptor system is involved in aggregation of a glycoprotein at regions of cell-cell or cell-substratum contact.

In lines such as Ric³14 which show lowered adhesiveness, and yet seem to contain normal levels of this component, the glycoprotein could bear a structural alteration affecting its function in adhesion, but not its presence at the cell surface.

Finally, although many ricin-resistant BHK cell lines resemble in adhesive properties certain lines of virus transformed cells¹⁶, none of the lines used in these experiments exhibits a transformed phenotype with respect to growth, since they grow poorly in low serum and in agar suspension, and yield saturation densities similar to the parental line.

Haemopoietic stem cells are organised for use on the basis of their generation-age

THE spleen-colony assay of Till and McCulloch¹, which is a clonal assay², measures the content of haemopoietic cells in blood-forming tissues. Stem cells (colony forming units in spleen, CFUS) form red cells, granulocytes, platelets and themselves (self-renewal) in these colonies^{3,4}. Worton *et al.*⁵ reported that stem cells separated by velocity sedimentation differed in their capacity for self-renewal. Schofield and Lajtha⁶ reported that CFUS from mice treated with isopropyl methane sulphonate have a low self-renewal capacity. We have studied the functional capacity of myeloid stem cells from normal mice (NBM) and mice treated with hydroxyurea. CFUS from mice treated with five injections of hydroxyurea (5 HUBM, G.S.H. and N. M. Blackett, unpublished) formed 3 times more CFUS and 2.5 times more colony forming units in culture per original colony (CFUC, a committed precursor of granulopoiesis⁷) than those from NBM. When these grafted CFUS were re-transplanted they still formed three times more CFUC and CFUS per secondary colony than those from NBM (Tables 1 and 2).

Table 1 Cellular products of the first graft of NBM and 5HUBM

Group	Colonies per spleen ±s.e.m.	CFUC per spleen ±s.e.m. (×10 ⁻⁶)	CFUC per colony ±s.e.m. (×10 ⁻³)	CFUS per original colony
IC	0.3±0.3	0		
NBM	34.8±1.3	1.46±0.34	4.23±1.0	43.2±2.3
5HUBM	51.3±1.9	5.53±0.61	10.84±1.26	128.2±8.3

NBM donors were 10 normal 3-month BALB/c female mice. 20 similar mice received hydroxyurea (Calbiochem) intraperitoneally (1 mg per g body weight) -32, -26, -10, -7 and -2 h before collection⁸. These were 5HUBM donors. Recipients were 2.5-3-month-old male and female BALB/c (20 mice per group). They were irradiated before grafting (700 R, 230 kVp (kilovolt peak)), HVL (half value layer) 0.5 mm Cu, 146 R.min., TSD (target-source distance) 50 cm., Maximar). Ten days after grafting half the recipients in each group were killed. Their spleens were fixed in formalin-acetic acid-ethanol (1:0.5:8.5) and the surface colonies counted. Twelve days after grafting the remaining recipients were killed. Their spleens were collected aseptically, passed through sterile stainless steel sieves and gauze and assayed individually for CFUC and in pooled groups for CFUS (20 recipients per group). CFUC were cultured in sealed, humidified boxes and counted on day 14. Control dishes with NBM (and the same source of colony-stimulating factor) formed 400 colonies per 10⁴ nucleated cells.

An hypothesis to explain these differences proposes that the use of haemopoietic stem cells to satisfy haemopoietic stress is based on the generation-age of these cells. A young stem cell is one that has undergone few generations since its origin, consequently its capacity for self-renewal and the production of committed precursors is greater than that of an older stem cell which has undergone more generations. Consider the differences between 5HUBM and NBM in the light of this proposal. The effect of the first two doses of hydroxyurea is to strip the haemopoietic tissues of dividing progenitors⁹ and, consequently, of their products. As a result CFUS move into cycle and are, in their turn, killed by further injections of hydroxyurea. It is assumed that the normal regulatory mechanisms bring the more mature CFUS from the pool of CFUS into cycle. On d 2 of treatment with hydroxyurea those cells in the S phase of the cell cycle are killed and the rest gathered at the G₁-S border by injections at -10 and -7 h. As the drug is cleared the blocked cells move into S and are killed by the fifth dose of hydroxyurea at -2 h. Those cells which survive the fifth dose of hydroxyurea are functionally more efficient than those which have survived four injections. (Spleenic DNA and blood ⁵⁹Fe uptake are more than 1.5 times greater and

Table 2 Cellular products of retransplanted stem cells from NBM and 5HUBM

Group	Cell dose in splenic equivalents of the primary graft	Colonies per spleen \pm s.e.m.	CFUC per spleen \pm s.e.m. ($\times 10^{-3}$)	CFUC per secondary colony \pm s.e.m. ($\times 10^{-3}$)	CFUS per secondary colony \pm s.e.m.
IC	0.03	3.9 \pm 1.3	0.01 \pm 0		
NBM	0.03	53.6 \pm 1.2	0.78 \pm 0.13	1.6 \pm 0.3	17.1 \pm 1.4
5HUBM	0.006	47.5 \pm 1.9	2.04 \pm 0.24	4.7 \pm 0.6	51.8 \pm 3.9

Experimental conditions were the same as those in Table 1 except that NBM controls in the CFUC assay formed 150 colonies per 10^4 nucleated cells

CFUC per colony almost 2 times greater (M.R., unpublished results.)

The hypothesis predicts that CFUS from foetal liver will have greater capacity for self-renewal than those from NBM and that stem cells, such as those in the blood whose capacity for self-renewal is less than that of NBM⁹, can be shown to be "older". Preliminary results confirm that this is so.

We should like to thank Julie Kerr and Lyndall Cropper for assistance.

Cellular and humoral immune responses in vaccination against dental caries in monkeys

PROTECTION against dental caries in the rhesus monkey by immunisation has now been characterised with respect to the development of *Streptococcus mutans*¹ and the corresponding antibodies²⁻⁴. One of the essential requirements for protection is the development of an optimum level of antibodies, at a critical time, before a large enough number of *Strept. mutans* has developed to initiate caries formation². Antibody synthesis, amplification mechanisms and protection depend on cellular interactions associated with T and B lymphocytes and macrophages⁵. The aims of this investigation were to study the part that cell-mediated immune responses might play in the protective mechanism against dental caries. The incidence of caries and the growth of *Strept. mutans* in rhesus monkeys was studied sequentially and compared with the development of serum antibodies, *in vitro* DNA synthesis of antigen stimulated lymphocytes, leukocyte migration inhibition (LMI) and *in vivo* skin delayed hypersensitivity (DH) to *Strept. mutans*.

Eight young rhesus monkeys were caged, examined and maintained on a human type of diet, containing 15% sucrose⁶. All animals had a fully erupted deciduous dentition and the permanent first molars were erupted in four monkeys; in the other four the permanent first molars erupted into a functional position within 30 weeks of the start of the experiment. As younger animals tend to develop more caries^{7,8}, the distribution of the monkeys was biased against the immunised group by including three of the younger monkeys without the permanent molars. A strain of

Strept. mutans (serotype c) was isolated from the dental plaque of a rhesus monkey which was used as a control in a previous experiment¹. The organism was grown in Todd-Hewitt broth, killed with 0.6% formalin, and a vaccine containing 2×10^9 *Strept. mutans* per ml was prepared². The three youngest monkeys were given subcutaneous injections of the vaccine mixed with an equal volume of Freund's incomplete adjuvant, 0.5 ml was injected into the right arm and 0.5 ml into the left leg at the start of the experiment. The same amount of *Strept. mutans* in saline was administered subcutaneously 30 weeks later. The sham-immunised group of three monkeys was given subcutaneous injections of 0.5 ml of saline instead of the vaccine. A further control group of two monkeys had no injections.

The animals were examined clinically and by means of X-rays for the presence of dental caries, they were weighed and blood was taken from the femoral vessels at 3-weekly intervals. At the same time, dental plaque was collected with a probe from the cervical and approximal surfaces of the upper left deciduous molars. The two control groups showed a very similar increase in caries and the number of colony-forming units (CFU) of *Strept. mutans*, so that they were combined for statistical analysis. Smooth surface (SS) caries was detected from week 18 (Fig. 1) and the mean rate of increase in caries in the immunised animals was significantly less than in the controls ($P < 0.05$). At week 54 a mean of $8.4 (\pm 1.2)$ cavities per animal was found in the controls compared with 2.7

Fig. 1 Sequential analysis of caries, antibodies and *Strept. mutans* in monkeys immunised with *Strept. mutans*. For antibody titration¹⁸ doubling dilutions of sera were added to air-dried smears of cells of the immunising *Strept. mutans* for 30 min, washed three times with phosphate-buffered saline (PBS), and then overlaid with anti-human IgG (F.P. 3.1), or IgM (F.P. 4.1) fluorescein-isothiocyanate conjugates (Wellcome). The reagents were checked for class specificity and cross reactivity with monkey IgG and IgM and specificity of the test was established by complete absorption of the antibody titre with the homologous and little or no absorption with heterologous organisms. The titres were expressed as $\log_2(1=1/5)$. *Strept. mutans* CFU are expressed as the percentage of total anaerobic colonies on TYC agar¹⁹, when dental plaque from the upper left deciduous molars was cultured for 48 h. Caries index is the number of smooth surface carious lesions detectable clinically or by means of X-rays². a, Immunised, b, sham-immunised.

(± 1.8) SS cavities per animal in the immunised group. Only three fissure caries lesions appeared by 54 weeks in the deciduous teeth of two of the five controls and in none of the immunised monkeys.

The decrease in the incidence of dental caries is consistent with the results of previous immunisation studies¹, but there were two major differences in the experimental design. A formalin-killed *Strep. mutans* organism, isolated from a rhesus monkey, was used, unlike the heat-killed human strain of *Strep. mutans* in the previous studies. Furthermore, unlike the six immunising injections in the first study² and five injections in the second study¹, only two injections were used at an interval of 30 weeks. Indeed it is not certain that the boosting injection was necessary, as the IgG antibody titre at that stage had decreased by only one dilution step.

Fig. 2 Skin DH to *Strep. mutans*. A sample of 0.05 ml of Mickle disintegrated cells of *Strep. mutans* (10^9 cells per ml) or physiological saline was injected intradermally into the shaved abdominal wall of each animal. Skin induration was measured with calipers at the times stated and expressed as the mean specific increase in skin thickness (\pm s.e.m.) due to *Strep. mutans*, after deduction of the skin thickness of the site injected with saline. a, Pre-immunised; b, sham-immunised; c, immunised.

Cutaneous delayed hypersensitivity was measured 24 weeks after the second immunising injection (Fig. 2). The mean (\pm s.e.) of skin induration of the three serial skin tests in each group of animals is given in Fig. 2 only for the broken cells, as the whole cells and culture extract failed to induce significant skin DH reactions. The results show a slight antigenic toxicity, in that the pre-immunised monkeys showed an induration of $1.0 (\pm 0.1)$ mm at 6 h (Fig. 2). The induration did not increase at 24 h, however, and decreased at 48 h. The sham-immunised monkeys showed a slight increase in induration from $1.42 (\pm 0.25)$ mm at 6 h to $1.62 (\pm 0.16)$ mm at 24 h and then a decrease at 48 and 72 h. In the immunised monkeys there was a significant increase from $1.42 (\pm 0.17)$ at 6 h to $2.23 (\pm 0.23)$ at 24 h ($P < 0.02$), to $2.54 (\pm 0.45)$ at 48 h ($P < 0.05$) and a decrease to $2.2 (\pm 0.45)$ at 72 h; the latter just failed to reach the 5% level of significance compared with the response at 6 h. The results indicate a skin DH reaction which reaches maximal value at 24–48 h.

When the lymphoproliferative response of the monkeys was examined, lymphocytes from pre-immunised and sham-immunised monkeys failed to respond to any of the *Strep. mutans* preparations, so that these were combined into one control group (Table

Table 2 Lymphoproliferative responses of T and B lymphocytes

Lymphocyte transformation was assessed as for Table 1. T lymphocytes were prepared by passing lymphocytes over nylon wool adherence columns¹⁶. B lymphocytes were obtained by depleting lymphocytes of cells rosetting with neuraminidase-treated ovine erythrocytes¹⁷, by Ficoll–Triosil gradient sedimentation. Cell purity was assessed by direct staining for surface immunoglobulin with fluorescein–isothiocyanate-labelled polyvalent anti-human Ig (Wellcome).

*No antigen

†*Strep. mutans* whole cell antigen

1). Significant differences between controls and immunised monkeys were found with the culture extract ($P < 0.001$), cell walls ($P < 0.01$) and whole cells ($P < 0.02$) of *Strep. mutans*, respectively, though only the whole cells yielded moderate stimulation index (SI). The cellular responses were limited to T lymphocytes, for 96–98% purified T cells yielded significant stimulation by antigens, whereas 94% enriched B lymphocytes failed to respond (Table 2).

Thus both the lymphoproliferative response and skin DH to the immunising antigens were found 24 weeks after the last immunisation, with a good correlation between the two tests for the experimental and control groups. In contrast, phytohaemagglutinin (PHA) did not show a difference between the immunised and control monkeys, but significantly increased SI to pokeweed mitogen (PWM) were found in the immunised monkeys ($P < 0.02$; Table 1). Although the differential response to the mitogens might have been due to the adjuvant, this is unlikely, as a comparison has been made between animals injected with saline and Freund's incomplete adjuvant (unpublished). There was no significant difference in the lymphoproliferative responses between the saline and adjuvant injected monkeys with PHA (5.7 ± 1.7 and 8.3 ± 3.4) and with PWM (10.5 ± 5.6 and 16.6 ± 8.8) respectively.

As the T- and B-cell mitogen (PWM), unlike the T-cell mitogen alone (PHA), showed a greater proliferative response in the immunised animals, this argues in favour of a heightened B-cell responsiveness in the immunised animals. This is consistent with the high antibody response maintained throughout the experimental period.

Serum IgG and IgM antibodies were assayed by the indirect fluorescent antibody (FA) test (Fig. 1). IgG antibodies increased within 3 weeks of immunisation to a mean \log_2 titre of $5.3 (\pm 1.2)$ which increased to an optimum titre of $\log_2 8.3 (\pm 0.35)$ by week 9 and this level was maintained throughout the experimental period. IgM antibodies were also increased but the titre was lower than that of IgG throughout the experimental period (Fig. 1). The titre

1×10^6 Ficoll–Triosil separated lymphocytes, in 1.0 ml of 10% autologous serum in medium TC199 (Wellcome), were cultured for 120 h¹⁸. Antigens in previously determined optimal concentrations were added in 0.1-ml amounts. PHA (Wellcome) was used at $50 \mu\text{g}$ per culture and PWM (Gibco) at $10 \mu\text{g}$ per culture. Cells were labelled with ^3H -thymidine ($1 \mu\text{Ci}$ per 10^6 cells) for the last 18 h of culture and collected using an automatic sampling device. The c.p.m. of unstimulated cells are shown \pm s.e.m. and SI is the ratio between antigen-stimulated and control cultures. NS, not significant.

*Only five monkeys tested.

Fig. 3 Relationship between IgG antibodies to *Streptococcus mutans* and lymphocyte transformation (a) or skin DH (b). IgG fluorescent antibodies were assayed as described in Fig. 1. a, Lymphocyte transformation as in Table 1. SI is the ratio of ³H-thymidine uptake in *Streptococcus mutans* whole cell-stimulated and control cultures after 120 h of culture with 1×10^6 Ficoll-Triosil separated lymphocytes, in 10% autologous serum in medium TC199. b, Skin testing for DH as in Fig. 2. Results shown are mean specific increases in skin thickness 48 h after injection of *Streptococcus mutans* broken cells.

was maintained from weeks 3 to 30 at a level of about log₂ 3–4, but in spite of the second immunising injection at week 30, the titre fell to a level of less than log₂ 2 by week 45. None of the control sera showed IgG or IgM fluorescent antibodies.

The finding of significant skin DH as well as antibodies in immunised monkeys raised the question of whether the DH might be a measure of T-cell helper function⁹. To enable us to analyse linear regression with some confidence, three further monkeys previously immunised with *Streptococcus mutans* (group c) were included. A significant positive correlation ($r=0.857$, $P<0.001$) was found between the 48-h skin induration and the IgG fluorescent antibody titre (Fig. 3b) and this is consistent with a T-cell helper function in antibody formation. As with the skin DH reaction a significant positive correlation (Fig. 3a), was found between the proliferative response of lymphocytes and the IgG antibodies to *Streptococcus mutans* ($r=0.884$, $P<0.001$). IgM was neither correlated with the skin DH reaction ($r=0.0826$, $P>0.1$) nor with the lymphoproliferative response ($r=0.411$, $P>0.1$). The protective mechanism against dental caries may thus be dependent on the helper function of T lymphocytes in generating IgG antibodies, as has been found in other systems¹⁰.

As another measure of cellular responses, lymphokine production was assayed by the leukocyte migration inhibition test (LMIT)¹¹. The results failed to distinguish between the two groups, as both the immunised (three of three) and sham-immunised (two of three) groups yielded significant LMI tested with whole cells of *Streptococcus mutans* (Table 3). This finding raised the possibility that conversion of LMI in the control monkeys was induced by the overgrowth of *Streptococcus mutans* in the bacterial plaque, as two of three sham-immunised monkeys also gave a positive LMIT with broken cells of *Streptococcus mutans*. Indeed, the LMIT in preimmunised monkeys which had not been exposed to the human cariogenic diet and had little or no *Streptococcus mutans* was consistently negative, supporting the view that sensitisation to *Streptococcus mutans* may have been induced through the gingival crevicular epithelium or the gut, by the increased load of *Streptococcus mutans* in the bacterial plaque.

Sequential analysis of the CFU of *Streptococcus mutans*, revealed consistently larger numbers of *Streptococcus mutans* in the control than in the immunised animals (Fig. 1). The results suggested that *Streptococcus mutans* were quantitatively related to the number of carious lesions in the control as well as the immunised groups, and that both the caries index and the number of *Streptococcus mutans* were decreased by immunisation.

It is also likely that not only the *Streptococcus mutans* antigen but also the adjuvant was required, as proposed by the modified "two signal model" in which an antigen-induced mitotic stimulus will result in the formation of a clone of antibody-forming cells only in the presence of a second, adjuvant stimulus¹². Indeed, negligible antibody titres and no lymphoproliferative responses were found on immunisation with *Streptococcus mutans* cells, without an adjuvant (unpublished).

In view of the great technical difficulties in monkeys of thymectomy *in vivo* or cell depletion *in vitro*, these have not been carried out. It is therefore not possible to draw definite conclusions as to T- and B-cell cooperation, though the results are consistent with the hypothesis that protection against *Streptococcus mutans* in dental caries involves T- and B-cell cooperation^{13,14}. This is based on finding: (1) a significant positive correlation between IgG antibodies and the proliferative response of lymphocytes to *Streptococcus mutans*, the latter being a function of T lymphocytes, and (2) a significant positive correlation between IgG antibodies and the skin DH reaction which may be a measure of T-cell helper function⁹.

This work was carried out under a project grant from the MRC. We thank Mr R. G. Ward and Mr J. K. Walton for technical assistance.

Table 3 Leukocyte migration inhibition test

Group	No.	No. of positive*, and (mean \pm s.e.) of migration index to <i>Streptococcus mutans</i>		
		Whole cells	Broken cells	Culture extract
Sham-immunised	3	2 (81.3 \pm 12.3)	2 (64.3 \pm 19.9)	1 (79.3 \pm 11.9)
Immunised	3	3 (74 \pm 2.2)	0 (86.7 \pm 2)	1 (90 \pm 11.3)
Preimmunised	3	0 (105.7 \pm 7.5)	0 (131.3 \pm 2.3)	0 (140.7 \pm 27.2)

Leukocytes were separated from peripheral blood using 3% dextran, washed twice and adjusted to 1×10^7 per ml in 10% horse serum with medium TC199. After filling, the capillary tubes (20 μ l) were plugged and centrifuged at 250g for 5 min, cut at the cell-fluid interface and placed in 1.0 ml of antigen-containing medium for 18 h in plastic chambers. Migration areas were recorded and measured by compensating planimetry. Migration index is the ratio between the area of leukocyte migration with and without antigen.

*Migration index < 80.

Ly phenotype of T-cells releasing T-cell replacing factor

THE Ly phenotype of T cells which cooperate with B cells in the production of antibody has been described as Ly 1⁺2⁻ (refs 1 and 2). Helper T cells are distinct from cytotoxic T cells (Ly 1⁻ Ly 2⁺)^{1,2} and suppressor T cells (Ly 1⁻ 2⁺)^{3,4}. In tissue culture, helper activity does not depend on the presence of intact T cells but can be mediated by cell-free supernatants from stimulated T cells. Stimulation with antigen induces the release of antigen-specific helper factors^{5,6} as well as factors which support antibody response against unrelated antigens⁷. Factors similar or identical to the latter are produced by splenic T cells in response to alloantigens⁸⁻¹⁰ and concanavalin A¹¹. It is tacitly assumed that the mechanism by which helper T cells collaborate with B cells in the production of antibody is to be attributed to the release of these mediators. We report here that with respect to their Ly phenotypes, T cells which release T-cell replacing factor (TRF)⁸ in response to alloantigen belong to the same subpopulation of T cells as helper cells.

In the experiments summarised in Table 1, TRF was generated in a one-way allogeneic reaction: spleen cells from C57BL/6 (B6) mice were cocultured with spleen cells from (B6×DBA/2)F₁ mice. The subpopulation of T cells responsible for TRF release was determined by cytolysis of

the B6 spleen cells with antisera directed against distinct T-cell alloantigens. Factor activity was assayed by its ability to restore antibody formation against sheep red blood cells (SRBCs) in cultures of T-cell depleted spleen cells from (B6×DBA/2)F₁ mice.

The production of TRF was completely abrogated after treatment with anti-Ly 1 serum or anti-Thy 1 serum and complement. Treatment by anti-Ly 2 serum and complement had no effect. Mixture of anti-Ly 2-treated cells with anti-Ly 1 or anti-Thy 1-treated populations, containing half as many cells of each kind compared with the unmixed populations, produced about 50% of the TRF activity achieved with untreated or anti-Ly 2-treated populations.

These data show that the presence of Ly 1⁺2⁻ T cells is sufficient for TRF production. Ly 1⁺2⁺ or Ly 1⁺2⁺ cells neither produce TRF nor contribute to the production of TRF.

2 × 10⁷ spleen cells per ml were suspended in 1 ml of 1:6 diluted anti-Ly 1.1 ((BALB/c × B6)F₁ anti-B6/Ly 1.1 thymocytes, absorbed with B6 thymocytes) or anti-Ly 2.2 ((C3H × B6/Ly 2.1)F₁ anti-B6 leukaemia ERLD, absorbed with B6/Ly 2.1 thymocytes) or 1:10 diluted anti-Thy 1.2 serum ((A/Thy 1.1 × AKR/H-2b)F₁ anti-A strain leukaemia ASL 1) or left untreated. After incubation for 30 min on ice, cells were washed with medium RPMI 1640 supplemented with 1% foetal calf serum. They were then resuspended at 1.5 × 10⁷ cells per ml in 1:24 diluted selected rabbit complement and incubated for 40 min at 37 °C. Cells were washed twice in medium and resuspended in equal volumes of medium such that the density of the complement control was 1.0 × 10⁷ cells per ml. To ensure serological specificity of anti-Ly antisera, the relevant congenic strain combinations were chosen. In the experimental group, spleen cells from the mouse strain B6/Ly 1.1 were treated with anti-Ly 1.1 or anti-Ly 2.2 antisera and complement. In control groups spleen cells of mice of the congenic strain B6/Ly 2.1 were treated with the same antisera and complement. In further control experiments all T cells were eliminated with anti-Thy-1.2 serum and complement. For the production of TRF⁸, equal volumes of B6 congenic cells (treated or untreated) and (B6 × DBA/2) F₁ spleen cells were cultured in standard conditions¹¹. Supernatants were collected after 24 h, passed through 0.45-µm Millipore filters and stored at -70 °C. The helper effect was evaluated using T-cell depleted BDF₁ spleen cells sensitised with SRBC (basically following the Mishell-Dutton culture method¹¹). 0.2 ml of anti-Thy-1.2-treated BDF₁ spleen cells adjusted to a volume corresponding to 2 × 10⁷ cells per ml in the complement control were added to multiwell plates (Falcon No. 3008), and 0.1-ml samples of the allogeneic supernatants described above or culture medium were added 24 h later. Plaque forming cells (PFCs) were determined by the Jerne haemolytic plaque assay after culture for 5 d. The data given are from one representative experiment. Repeat experiments gave similar results.

Role of chloride transport in regulation of intracellular pH

It is well known that introducing acid into a cell causes a rapid fall in intracellular pH (pH_i) which is followed by a slower rise¹⁻⁵. Since this return of pH_i towards its original value could not be accounted for by the passive transmembrane movement of H^+ , OH^- , or HCO_3^- , it was ascribed to the active removal of acid from the cell^{1,2}. In the squid giant axon, this acid extrusion is reversibly blocked by cyanide and greatly enhanced by HCO_3^-/CO_2 (ref. 3). More recently, it has been found that acid extrusion in the snail neurone also is stimulated by HCO_3^-/CO_2 (ref. 4), and that, in addition, it is inhibited by 4-acetamido-4'-isothiocyano-stilbene-2,2'-disulphonic acid (SITS)⁵, a known inhibitor of anion fluxes in erythrocytes⁶. In this respect it is interesting to note that a component of Cl^- efflux in barnacle muscle also is stimulated by HCO_3^-/CO_2 and blocked by SITS⁷. We now report that acid extrusion in the squid axon requires internal Cl^- and ATP, that it is blocked by SITS, and that it is accompanied by the SITS-sensitive efflux of an equivalent amount of Cl^- . These observations suggest that acid extrusion actually involves the neutral exchange of external HCO_3^- for internal Cl^- .

Our experiments were carried out on giant axons of the squid *Loligo pealei*. To control the intracellular concentrations of low molecular weight solutes, we used the internal dialysis technique⁸: porous dialysis capillaries were introduced into cannulated axons, and flushed with solutions of known composition. In one series of experiments, pH_i was monitored by placing

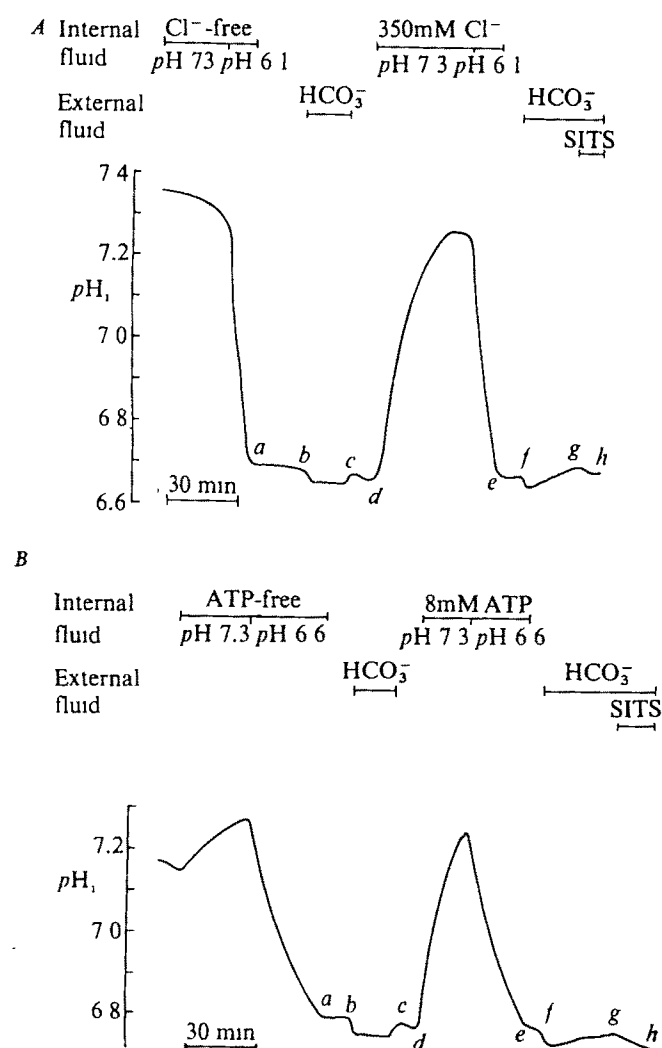

Fig. 2 $^{35}Cl^-$ efflux from internally dialysed squid axons. **a** ATP-dependence of HCO_3^- -stimulated Cl^- efflux. The axon was dialysed with a solution containing 150 mM Cl^- , and at zero time the flow of isotope-containing dialysis fluid was begun. The fluid superfusing the axon contained nominally 2 mM NaCN and was collected at 3- or 4-min intervals. An appropriate volume of a 2:1 toluene-Triton X-100 scintillation mixture was added¹⁰ and the samples counted long enough to achieve at least a 5% counting accuracy. There was no stimulation of $^{35}Cl^-$ efflux by 10 mM $HCO_3^-/0.4\% CO_2$ unless the dialysis fluid contained ATP. V_m was -60 mV at the beginning of this experiment, and -53 mV at the end. **b** and **c**, Effect of 0.5 mM SITS on HCO_3^-/CO_2 -stimulated Cl^- efflux. In the experiment represented in **b** $^{35}Cl^-$ efflux fell when the HCO_3^-/CO_2 was removed from the ASW ($V_m = -60$ mV). In **c**, however, where the axon had been pretreated for 50 min with 0.5 mM SITS, removal of the HCO_3^-/CO_2 had no effect ($V_m = -64$ mV). In four axons, 0.5 mM SITS caused the HCO_3^-/CO_2 -stimulated Cl^- efflux to decline from 10.1 ± 1.5 to 7.2 ± 1.0 pmol $cm^{-2} s^{-1}$. pH of dialysis solution 6.8; temperature 15 °C.

Fig. 1 **A**, Effect of $(Cl^-)_i$ on the acid extrusion. The axon was dialysed first with Cl^- -free (glutamate replacing Cl^-) and then with 350 mM Cl^- fluid, while pH_i was monitored with a glass electrode. In the absence of internal Cl^- , HCO_3^-/CO_2 (segment **bc**) did not stimulate acid extrusion ($n = 17$), whereas in the presence of 350 or 150 mM Cl^- (not shown), HCO_3^-/CO_2 (**fg**) did stimulate acid extrusion ($n = 14$). SITS 0.5 mM (**gh**) blocked the HCO_3^- -stimulated acid extrusion ($n = 7$). Membrane potential (V_m) was -57 mV at the outset of this experiment, and -47 mV at the end. The period of dialysis was always at least 40 min, a length of time sufficient to attain isotopic equilibration with $^{35}Cl^-$ (see Fig. 2). In the low Cl^- ASW, NaCl and KCl were replaced by sodium isethionate and $MgCl_2$ by $MgSO_4$. **B**, ATP dependence of acid extrusion. The axon, pretreated for 1 h in nominally 2 mM NaCN ASW, was dialysed first with an ATP-free and then with an 8 mM ATP solution (150 mM Cl^-). Although HCO_3^-/CO_2 failed to stimulate acid extrusion in the absence of internal ATP (**bc**), HCO_3^-/CO_2 did stimulate this extrusion when ATP (**fg**) was present ($n = 3$). The acidification during **ef**, which probably reflects breakdown of the exogenous ATP, was minimised by pretreating the axon with 10^{-6} M ouabain and by including oligomycin ($12 \mu g ml^{-1}$) in the dialysis fluid. In this experiment, the initial and final V_m was -61 mV. Temperature of both experiments 22 °C. The pH of the 10 mM $HCO_3^-/0.4\% CO_2$ ASW was 8.0; all other ASWs in this study had a pH of 7.7. Unless otherwise noted, the composition of the dialysis fluid was (mM): 150 KCl, 200 K glutamate, 50 Na glutamate, 4 $MgSO_4$, 190 taurine, 0.5 EGTA, 10 HEPES and 0.5 phenol red.

pH-sensitive and reference microelectrodes into the axon² alongside the dialysis capillary. In the other series, Cl⁻ efflux was measured in axons dialysed with solutions containing ³⁶Cl⁻.

The dependence of acid extrusion on internal Cl⁻ was investigated by measuring this extrusion, both in the presence and absence of internal Cl⁻. The axon of Fig 1A was superfused with low (20 mM) Cl⁻ seawater, and was first dialysed with a Cl⁻-free solution (pH 7.3). Acid was then introduced into the axon by lowering the pH of the dialysis fluid to 6.1. When the pH_i had fallen to 6.7 (point *a*), the flow of dialysis fluid was halted so that the subsequent course of pH_i was determined by cellular processes. In a normal axon, this fall in pH_i (acid challenge) would be followed by a rise, the rate of this alkalisation being an index of acid extrusion. In this axon depleted of internal Cl⁻, however, pH_i continued to fall (segment *ab*). Moreover, HCO₃⁻/CO₂ failed to reverse this decline (*bc*). In contrast, when Cl⁻ was reintroduced into the axon by dialysing with a 350 mM Cl⁻ solution, and the pH_i was once more reduced to 6.7 (*e*), HCO₃⁻-stimulated acid extrusion was observed (*ef*). Dialysis with 150 mM Cl⁻ gave identical results (not shown). Treating the axon with 0.5 mM SITS (*gh*) blocked the HCO₃⁻-stimulated acid extrusion.

Fig. 3 Proposed scheme for acid extrusion. An ATP-dependent mechanism would inject external HCO₃⁻ in exchange for internal Cl⁻. Once inside, the HCO₃⁻ would combine with H⁺ to produce CO₂ + H₂O, which would then leave the cell and yield H⁺ + HCO₃⁻ once again. The net effect is to eject HCl from the cell.

The previously described inhibition of acid extrusion by cyanide³ suggested that acid extrusion might require ATP. One can reduce internal ATP to very low levels by dialysing with an ATP-free solution in the presence of cyanide⁹. In this manner, we lowered (ATP), in the axon of Fig 1B, and then challenged the axon with acid. No alkalisation (that is, no acid extrusion) was observed when dialysis was halted (*a*) even in the presence of HCO₃⁻/CO₂ (*bc*). When the axon was dialysed with an ATP-containing solution (*d*) in the continued presence of cyanide and then challenged with acid, the pH_i continued to fall (*ef*) after cessation of dialysis (possibly due to breakdown of exogenous ATP). But this decline was reversed when HCO₃⁻/CO₂ was added (*fg*). SITS again blocked this acid extrusion (*gh*), causing pH_i to fall at about the same rate as in segment *ef*.

The preceding experiments show that internal Cl⁻ and ATP are required for HCO₃⁻-stimulated, SITS-sensitive acid extrusion. The evidence that externally applied HCO₃⁻/CO₂ enhances Cl⁻ efflux from barnacle muscle, and that this HCO₃⁻-stimulated efflux is similarly SITS sensitive⁷ prompted us to consider the possibility that Cl⁻ efflux is linked to acid extrusion. We found that at relatively high pH_i, adding 10 mM HCO₃⁻/0.4% CO₂ had very little effect on acid extrusion. Similarly, we found that in these conditions (pH_i 7.3), 10 mM HCO₃⁻/0.4% CO₂ does not significantly increase Cl⁻ efflux. When the pH_i was lowered to about 6.7 by dialysis, however, both acid extrusion (Fig. 1) and Cl⁻ efflux were found to be enhanced by HCO₃⁻/CO₂: in 12 experiments 10 mM HCO₃⁻/0.4% CO₂ increased Cl⁻ efflux from 7.7 ± 0.6 (s.e.m.) to 11.6 ± 1.0 pmol cm⁻² s⁻¹ (15 °C). The response of Cl⁻ efflux and acid extrusion to removal of ATP provides another point of comparison between the two processes. As was the case with acid extrusion (Fig. 1B), Cl⁻ efflux did not respond to HCO₃⁻/CO₂ when the axon was deprived of ATP (Fig. 2a); responsiveness was restored when ATP was added to the dialysis fluid. In addition, just as with acid extrusion, HCO₃⁻/CO₂ stimulation of Cl⁻ efflux was inhibited by SITS, as can be seen by comparing Fig. 2b and c.

Thus, both HCO₃⁻-stimulated acid extrusion and Cl⁻ efflux require ATP and are blocked by SITS. In three acid extrusion experiments in which the temperature was the same as in the Cl⁻ studies (15 °C), HCO₃⁻-stimulated acid extrusion was estimated to be 4.8 ± 0.9 pmol cm⁻² s⁻¹, rather close to the HCO₃⁻-stimulated Cl⁻ efflux (3.9 pmol cm⁻² s⁻¹). It is attractive to hypothesise (Fig. 3) that the squid axon possesses an ATP-dependent pump which responds to acid challenges by taking up HCO₃⁻ from the external solution and extruding an equivalent amount of Cl⁻. Since the entering HCO₃⁻ is converted to CO₂ and H₂O, both of which subsequently leave the axon, the net effect of this transport mechanism is to extrude HCl.

Acetylcholine receptor degradation measured by pulse chase labelling

THERE is increasing evidence that the turnover of the cholinergic receptor protein in developing or adult muscle fibres varies in the course of synaptogenesis or as a consequence of denervation^{1,2}. Muscle activity is involved in this regulation³, but the mechanisms of the control processes and the chemical signals which mediate these effects remain largely unknown.

To investigate this question several methods have been developed for the measurement of acetylcholine-receptor (AChR) turnover in embryonic muscle in tissue culture⁴ and denervated or neonatal rat diaphragm⁵. We present

here quantitative methods for the direct measurement of AChR turnover which depend on the incorporation of the radioactive precursor ^{35}S -L-methionine into newly synthesised receptor polypeptides and subsequently purification of radioactive receptor by affinity chromatography (ref. 4 and manuscript in preparation). These techniques have been applied to the determination of receptor half life in primary tissue cultures of foetal calf skeletal muscle. Results reported here indicate that AChR polypeptides with toxin binding activity have a half life of about 17 h. This value is identical to that obtained indirectly by measurement of the degradation of ^{125}I - α -bungarotoxin (^{125}I -BuTx) bound to receptor sites.

To measure directly the degradation of AChR, cultures of dissociated foetal calf skeletal muscle cells were pulse labelled with ^{35}S -L-methionine (10 Ci mmol^{-1} , CEA, France) for 7 h, 90 h after establishment of the cultures^{4,5}. After washing, the cells were chased with myoblast conditioned medium supplemented with $5 \times 10^{-5}\text{ M}$ L-methionine. At different times after the chase, 10 culture dishes were washed with warmed phosphate buffer saline (PBS) and stored at -80°C . AChR was purified from labelled cells by techniques described previously⁴ with the modifications indicated in the legend to Table 1.

Table 1 is a summary of AChR purifications from two pulse chase experiments. In every case, receptor activity (as determined by ^{125}I -BuTx binding assay⁶) from the labelled extract was quantitatively adsorbed to the affinity support of Erabutoxin-b coupled to Sepharose 4B (data not shown). The yield of each purification was therefore dependent on the efficiency of specific elution by the cholinergic agonist decamethonium. As can be seen in column C, Table 1, the yield or % recovery of toxin binding sites from different purifications varied from 11 to 29%. The observed variability is attributed to variation in specific elution from the affinity support. Recent experiments have shown that the receptor not recovered by decamethonium elution remains bound to the affinity support, suggesting it is not recovered in an inactive form.

Fig. 1. Column purified receptor activity, after removal of decamethonium on DE-52 cellulose, was incubated at 4°C with ^3H - α -toxin from *N. nigricolis*, and normal or anti-*E. electricus* acetylcholine receptor rabbit serum. These incubations were centrifuged in isokinetic 10–40% sucrose gradients for 24 h at 40,000 r.p.m. in Beckman SW 41 rotor^{4,12}. Fractions were collected from the bottom of the tube and counted in Triton containing scintillation cocktail¹³ for ^3H (solid line) and ^{35}S (dashed line).

Cells were labelled as described in the text. Frozen cells were scraped from the plates in distilled water. The water extracts were centrifuged at $100,000g$ for 30 min. The membrane pellet was suspended in 1% Triton X-100 in 0.18 M NaCl, 0.025 M, NaH_2PO_4 , pH 7.6 containing 10^{-4} M phenylmethylsulphonyl fluoride, 10^{-4} M benzethonium chloride and 10^{-3} M EDTA to inhibit protease activity¹⁴. After extraction for 2 h at 4°C , the extract was centrifuged at $100,000g$ for 30 min. The supernatant was removed and filtered through a plug of glass wool. Triton extracts were adsorbed to an excess of affinity support, consisting of Erabutoxin b, coupled to cyanogen bromide, activated Sepharose 4B ($100\text{ }\mu\text{g ml}^{-1}$)¹⁴. Adsorption was complete ($>80\%$) in 3–5 h. After the complete adsorption of receptor activity from the ^{35}S -labelled extracts, the affinity columns were incubated with an excess of cold crude extract containing receptor. Receptor adsorption was monitored by the ^{125}I -BuTx binding assay. Column A is the amount of total toxin-binding activity. (^{35}S labelled plus cold) bound to the column. The columns were washed with 0.36 M NaCl, 0.05 M NaH_2PO_4 , pH 7.6, 1% Triton, until the level of ^{35}S radioactivity in the wash was reduced to background. Toxin binding activity was released from the column by incubation with 0.1 M decamethonium at 4°C for 40 h. After dilution, the toxin column eluates were adsorbed to and eluted from DE-52 cellulose columns to remove decamethonium. The toxin-binding activity was then assayed by ^{125}I -BuTx binding. The yield of each purification was calculated from the toxin-binding activity recovered relative to that initially bound, column C. Total ^{35}S -methionine c.p.m., column D, was determined by hot TCA precipitation of an aliquot of the crude water extract. The amount of AChR ^{35}S -methionine c.p.m. was determined by analysis of the toxin column purified material (after DE-52 chromatography) on sucrose gradients. Complete recovery of input ^{35}S c.p.m. was obtained. Only the 9S toxin binding peak was summed and recorded in column E. Finally, these values were corrected to 100% recovery, column F.

Fig. 2 AChR degradation. The corrected values for AChR 35 S-c.p.m. remaining after the chase from Table 1 were normalised to a zero time 100% figure and plotted here as a first-order decay as open and filled triangles for the two separate experiments. The total protein 35 S-c.p.m. was similarly normalised and plotted as open and closed squares. The loss of bound 125 I-BuTx was studied as described by Devreotes and Fambrough⁴. Cells were incubated with 125 I-BuTx (prepared as described by Vogel *et al.*, 1972 (ref. 13) overnight at a concentration of 5×10^{-9} M. Unbound toxin was washed free by six successive washes with warmed complete culture medium. Finally, cells were returned to the culture with complete myoblast conditioned medium. At different times, four labelled plates were washed several times with PBS and scraped in 1% Triton X-100, 0.18 M NaCl, 0.025 M NaH_2PO_4 (pH 7.6). These extracts were counted directly in a gamma counter. All values from two independent experiments were normalised to a zero time of 100% and were plotted as open and closed circles.

At each step of the purification, the 35 S-methionine content of the sample was determined by scintillation counting. Column D, Table 1, lists the total hot trichloroacetic acid precipitable material. In column E is recorded the summed 35 S-methionine radioactivity of the affinity purified receptor which was observed to cosediment with the 9S peak of toxin-binding activity in a 10–40% isokinetic sucrose gradient^{1,12}. The fraction of 35 S-c.p.m. thus sedimenting represented 63–83% of the total in the gradient and was quantitatively shifted to a more rapidly sedimenting form by preincubation with rabbit antiserum prepared against purified AChR from *Electrophorus electricus*. One example of such an analysis is shown in Fig. 1 (ref. 4). Furthermore, the affinity purified material was found to be of high purity by two-dimensional high resolution gel electrophoresis (ref. 7 and J.P.M., manuscript in preparation).

The values obtained by sucrose gradient analysis were finally corrected for variation in the yield and are recorded in column F. It can be calculated that the synthesis of ACh receptor makes up only a very small fraction of global protein synthesis, about 0.065% in experiment 1 and 0.016% in experiment 2.

To calculate a receptor half life from the experimental data in Table 1, the values in column F were normalised to a zero time figure of 100%. In a similar fashion, a mean half time was calculated for total protein values in column D. The respective half lives were 17 h for the AChR and 48 h for total protein.

The value of 17 h for ACh-receptor half life by direct pulse chase experiments is in good agreement with values previously published for AChR from chick skeletal myotubes in cultures^{1,8} and extra synaptic receptor of denervated rat diaphragm^{2,9}. All of these previous measurements have been made by the indirect method in which the

degradation of bound 125 I-BuTx is observed. We have confirmed the half-life measurements by the indirect method in our tissue culture system and have found a value of 17 h, identical to that determined by the pulse chase experiments. This agreement lends support to the argument that the toxin-binding method is a valid probe of receptor metabolism^{2,9}.

From studies of loss of bound toxin to denervated or embryonic rat diaphragm, two rates of receptor degradation have been suggested^{9,10}. One, extrasynaptic, with a relatively high rate of turnover having a T_1 of 8–22 h, and a second more stable, synaptic, species with $T_1 > 100$ h. The reason for this considerable difference in degradation rate is not known. Furthermore, there is indirect evidence that the activity dependent alteration of extrasynaptic receptor levels is regulated at the level of polypeptide synthesis^{11,12}. Quantitative studies of receptor synthesis making use of the technique applied here to receptor degradation should permit the elucidation of the control mechanisms involved in the steady-state level of ACh receptor. It will be possible to determine how nerve-induced muscle activity functions to signal alterations in macromolecular synthesis, at what level (transcriptional or translational) is receptor synthesis controlled and what are the precursor-product relationships between synaptic and extrasynaptic receptor.

Anticholinergic and membrane activities of amantadine in neuromuscular transmission

AMANTADINE hydrochloride (1-adamantanamine hydrochloride, Symmetrel) is an antiviral agent which prevents certain viruses from penetrating cells^{1–3}. In addition, this drug is also effective in relieving clinical symptoms shown in parkinsonism^{4–8}; this action of amantadine may depend on its capacity to increase the synthesis and release of dopamine from dopaminergic cells of the basal ganglia^{9,10}. To obtain additional evidence which might aid in explaining

these remarkably diverse effects of amantadine, we used single-cell electrophysiological techniques to study its action on junctional and extrajunctional membranes. Our results show that amantadine, in clinically effective concentrations, rapidly inhibits neuromuscular transmission, and when applied over a longer period of time the drug also exerts a substantial effect on the conductile membranes of muscle fibres.

In the first series of experiments we studied the action of amantadine on the indirectly-stimulated nerve-muscle preparation. Frog (*Rana pipiens*) sartorius muscle-sciatic nerve preparations were bathed in HEPES-buffered Ringer solution (112.4 mM Na⁺, 2.5 mM K⁺, 1.8 mM Ca²⁺, 117.1 mM Cl⁻, 3.0 mM HEPES buffer, pH 7.4) bubbled with 100% oxygen and containing dextrose (1 g l⁻¹). The sciatic nerve was stimulated electrically (0.1 ms min⁻¹) at a level 2.5 times that required for initiating the maximal isometric tension output. When the tension output had become constant, the preparation was curarised in two stages to produce a stable partial neuromuscular block¹¹. The nerve and muscle were first soaked for 10 min in HEPES-buffered Ringer solution containing 14 μ M *d*-tubocurarine (*d*TC) after which the *d*TC concentration was reduced to 0.7 μ M for the remainder of the experiment. Amantadine was added to the bath only after muscle tension output in the *d*TC-treated preparation had been stable for at least 60 min. For experiments where resting potentials (r.p.s), action potentials (a.p.s), endplate potentials (e.p.p.s) and miniature endplate potentials (m.e.p.p.s) were recorded intracellularly, the cutaneous pectoris nerve-muscle preparation was used *in vitro*. The preparation was bathed in HEPES-buffer Ringer solution, and where e.p.p.s were recorded, the two-stage curarisation technique described above was used. All experiments were done at room temperature (19–25 °C).

The results of isometric tension output measurements in partially curarised muscle are shown in Fig. 1. It can be seen that application of amantadine produced a simple reduction tension output which was reversed when this drug was removed. In three additional experiments, amantadine was applied to non-curarised nerve-muscle preparations. At 800 μ M amantadine, the tension output was reduced to 35% of control after 40 min exposure to the drug. At 500 μ M amantadine, the tension output fell to 60% of control after 55 min of drug application. Amantadine at 150 μ M did not produce a reduction in muscle tension output.

In the next series of experiments, e.p.p.s were recorded intracellularly from single muscle fibres of the curarised cutaneous pectoris muscle while nerve stimuli were applied once every 10 s. After a 30-s control period, for which three e.p.p.s were recorded and averaged, the junctional region was microperfused with bathing solution containing either 50 or 150 μ M amantadine. As shown in Fig. 2, the e.p.p.s were immediately and progressively reduced in

Fig. 1 Effect of amantadine on the isometric tension output of partially curarised, indirectly-stimulated sartorius muscle-sciatic nerve preparation of frog. Average of three muscles. Aman, amantadine.

amplitude following application of amantadine. During the 8-min period following cessation of amantadine application, the e.p.p. amplitude rose but did not reach the control value. The incomplete recovery is partially the result of a 10–12-mV fall in r.p. which occurred during the recording because the muscle twitch was not completely blocked in these experiments. More complete recovery would probably have occurred if additional time had been allowed, and if the muscle had been washed with amantadine-free bathing solution.

In the next group of experiments we showed that the slow reduction of resting potential observed in the previous experiments is not produced as a result of a postjunctional depolarising action of amantadine. The nerve-muscle preparation was treated as before with HEPES-Ringer solution plus *d*TC (two stages) but in this case only one e.p.p. was recorded from each individual muscle fibre of the sample group. Thereafter the muscle was bathed in HEPES-Ringer solution containing *d*TC plus amantadine (50 or 150 μ M) and a single e.p.p. was recorded from an additional group of individual fibres over a period of the next 30 min. The results of such experiments are summarised in Table 1. They show that there is a rapid reduction in the amplitude of the e.p.p. to 40% of control during the first 5 min of exposure to 50 μ M amantadine, and a reduction to 10% of control follows 5 min of exposure to 150 μ M amantadine. It can be seen that amantadine progressively depresses the amplitude of the e.p.p. during the entire 30-min period of its application, and it is also evident that amantadine does not depolarise the postjunctional membrane under these conditions.

Table 1 Effect of amantadine on resting potential and endplate potentials of partially curarised frog muscle fibres

No. of muscles	Amantadine (μ M)	Duration of soaking (min)	r.p. (mV)	n	e.p.p. (mV)	n

* Standard error of mean.
n, Number of fibres.

The local perfusion technique was also employed to observe the effects of amantadine on the amplitude and frequency of m.e.p.p.s. Microperfusion of two endplates with Ringer solution containing 300 μ M amantadine reduced the m.e.p.p. amplitude to zero in 12–48 s and the amplitude recovered to 70–85% of control 7 min after amantadine application had ceased. With 150 μ M amantadine, the m.e.p.p. amplitude in three endplates fell to 40–55% of control in 1 min and recovery was 65–90% complete in 5–7 min. At 50 μ M amantadine the m.e.p.p. amplitude in two endplates was reduced to 50% in 2 min and recovered to 70–80% in 4–7 min. The time course for depression and recovery of m.e.p.p. amplitude observed in these experiments was similar to that shown by e.p.p.s in the previous experiments. Amantadine at 50 and 150 μ M seemed to reduce the m.e.p.p. frequency but this limited observation needs verification, partly because amantadine reduces m.e.p.p. amplitude and thus the frequency count may be inaccurate because some low amplitude m.e.p.p.s may have gone undetected in the baseline noise of our recordings.

We have so far provided evidence that amantadine at 50 and 150 μ M has significant blocking action at the frog neuromuscular junction since it causes reduction in the tension output of the indirectly stimulated, partially curarised nerve-muscle preparation, and it also substantially reduces the amplitudes of e.p.p.s and m.e.p.p.s. The reduction in the amplitudes of m.e.p.p.s and e.p.p.s may be interpreted on the basis that amantadine reduces the sensitivity of the postjunctional membrane to acetylcholine and the following experiments were carried out to test this supposition. Local perfusion of nine junctions (three muscles) with 100 μ M amantadine reduced the m.e.p.p. amplitude from a control value of 0.35 mV to 0.11 mV in ~ 25 s. The m.e.p.p. frequency (min^{-1}) fell from 37 (control) to 15. In seven of these perfused junctions which were tested for response to nerve stimulation, five showed block of neuromuscular transmission (average e.p.p. amplitude 18 mV). During iontophoretic application of 5-ms pulses of carbamylcholine to the postjunctional membrane, microperfusion with 100 μ M amantadine reduced the carb depolarisations from 2.1 mV (control) to 0.3 mV in ~ 70 s (nine fibres). Thus the reduction in postjunctional sensitivity produced by amantadine is sufficient to account for its rapid action in reducing the amplitude of m.e.p.p.s and e.p.p.s and hence in causing a block in neuromuscular transmission.

Fig. 2 Effect of amantadine on the amplitudes of endplate potentials recorded from partially curarised muscle fibres. ○, average of five endplates, 50 μ M amantadine; ▲, average of six endplates, 150 μ M amantadine.

In the final series of experiments, we investigated the direct action of amantadine on the muscle fibre conductile membrane. No change in r.p. or a.p. was produced during the first 30 min of application of 150 μ M amantadine. After 1 h of exposure to 150 μ M amantadine, however, depolarisation of the muscle fibres was evident and thereafter the depolarisation increased steadily with time. From Table 2, it may be seen that the average reduction of the resting potential was 8 mV between the first and second hour, and 18 mV during the second to third hour of exposure to 150 μ M amantadine. In addition, the amplitude, rate of rise and rate of fall of the a.p. were significantly reduced by application of 150 μ M amantadine for these time periods.

The results of our study indicate that amantadine rapidly inhibits neuromuscular transmission by reducing the response of the muscle postjunctional membrane to acetylcholine. When applied for relatively prolonged periods, it affects the resting and action potentials of extrajunctional excitable membranes. If amantadine produces similar changes in the resting and action potentials of the pre-synaptic neuronal membrane, one might predict that this drug would reduce the quantal output per nerve impulse. Unfortunately, it is not feasible to test this speculation by using the usual experimental methods because amantadine strongly inhibits postjunctional cholinergic receptors.

We suggest that the beneficial effect of amantadine in parkinsonism may depend to some extent on the capacity of this drug to inhibit cholinergic transmission in certain neuronal circuits involved in the central control of muscular movement. The demonstrated action of amantadine on extrajunctional membranes may provide a route whereby the mode of action of this drug in preventing penetration of cells by viruses may ultimately be understood.

Evidence for a prejunctional role of cyclic nucleotides in neuromuscular transmission

THERE is evidence for¹⁻³ and against^{4,5} the involvement of cyclic nucleotides in the release of neurotransmitters. We have investigated this question using a method more suited to the detection of prejunctional drug actions than those used previously. Instead of trying to infer the action of nucleotides on nerve endings by recording endplate potentials or muscle contractions *in vitro*, we recorded from single motor axons of cat soleus nerves *in vivo*. We found that dibutyl (db) cyclic AMP initiated activity in unstimulated motor axons and produced stimulus-bound AMP, db cyclic GMP, sodium butyrate and 5' AMP had no repetitive activity (SBR) in stimulated axons, whereas cyclic repeat. NaF and theophylline also initiated activity in unstimulated axons and produced SBR in stimulated axons. Pretreatment with the theophylline potentiated the effects of db cyclic AMP or NaF. The results suggest that cyclic AMP is involved in the excitation-secretion sequence of mammalian motor nerve endings.

The preparations have been described before.⁶ Cats were anaesthetised with α -chloralose (70 mg kg⁻¹), the popliteal fossa was dissected and all branches of the tibial nerve except that to the soleus muscle were cut. Similarly, all branches of the popliteal artery except the posterior tibial were occluded. Both heads of the gastrocnemius muscle were removed and the tendon of the soleus muscle was attached to a strain gauge. Dorsal laminectomy (L4-S1) exposed the ventral root of spinal nerve L7, which was severed close to the cord and its distal stump divided until a strand containing a single active axon to the soleus nerve was found. The strand was placed across bipolar platinum recording electrodes. A bipolar platinum stimulating electrode was placed on the soleus nerve and a

Fig. 1 *a*, SBR produced in a soleus motor axon by db cyclic AMP. The first trace shows the response to a single stimulus applied before the drug. Subsequent traces show the responses to similar stimuli applied once every 2.5 s after the administration of db cyclic AMP (100 µg kg⁻¹). The time mark represents 5 ms. *b*, Effects of db cyclic AMP on the force of contraction of the soleus muscle. The left record represents the response produced by administration of the agent (arrow, 100 µg kg⁻¹ intra-arterial) to a neurally stimulated muscle. The middle record represents the response to db cyclic AMP (arrow, 200 µg kg⁻¹ intra-arterial) of an unstimulated muscle. The right record represents the effect of the agent (arrow, 200 µg kg⁻¹ intra-arterial) on a chronically denervated muscle.

supramaximal pulse lasting 0.1 ms was applied every 2.5 s.

Denervated muscles were prepared by anaesthetising cats with intramuscular ketamine (25 mg kg⁻¹) and aseptically cutting the sciatic nerve at the sciatic notch. Two weeks later the animal was anaesthetised with intravenous chloralose (70 mg kg⁻¹) and the leg was prepared and mounted as before. A pair of electrodes was formed by sewing 33-gauge stainless steel wire in two series of concentric loops at the tendonous end of the muscle. A supra-maximal pulse lasting 2 ms was applied every 2.5 s.

Seven reagents were used. The first three, *N*²-*O*-dibutyl-adenosine-3',5'-monophosphoric acid, cyclic (db cyclic AMP), *N*²-*O*-dibutyl-guanosine-3',5'-monophosphoric acid, cyclic (db cyclic GMP) and adenosine-3',5'-monophosphoric acid, cyclic (cyclic AMP) are nucleotide derivatives. Of these, the first two cross cell membranes easily, while the last does not. The fourth, NaF, is an activator of adenylate cyclase⁷, the fifth, theophylline, is an inhibitor of phosphodiesterase and the last two, sodium butyrate and 5' adenosine monophosphate (5'AMP), are hydrolysis products of db cyclic AMP. Each compound was dissolved in 0.85% NaCl solution so that 0.1 ml contained the amount to be administered per kg, and 0.1 ml per kg of the solution was injected into the popliteal artery.

Dibutyl cyclic AMP in doses ranging from 50 to 200 µg kg⁻¹ caused SBR in motor axons (Fig. 1), with maximum intensity occurring after the first stimulus after the injection—less than 2.5 s after injection. Repetitive potentials were of high frequency, 300-400 Hz, but the train after each stimulus was always less than 12 ms. Neural activity was transmitted to the muscle where it caused repetitive activation and a brief tetanic contraction stronger than the simple twitch of the control period. This

Fig. 2 *a*, SBR produced in a soleus motor axon by NaF. The first trace shows the response to a single stimulus applied before the drug. Subsequent traces show the responses to similar stimuli applied at the given time intervals after the intra-arterial administration of NaF ($200 \mu\text{g kg}^{-1}$). Time mark represents 5 ms. *b*, Effects of intra-arterial NaF (arrows) on the force of contraction of the soleus muscle. The first two records represent the effects of 50 and $200 \mu\text{g kg}^{-1}$, respectively, on a neurally stimulated preparation. The third trace represents the effect of $400 \mu\text{g kg}^{-1}$ on a chronically denervated muscle.

is shown in the mechanograms of Fig. 1, which also shows that the intensity, duration and time course of the repetitive activity were related to the dose of db cyclic AMP. Larger doses of db cyclic AMP ($> 100 \mu\text{g kg}^{-1}$) also initiated activity in unstimulated preparations. Immediately after injection, bursts of action potentials appeared in the nerve and the muscle underwent a series of rapid asynchronous contractions, causing the baseline of the record to rise (Fig. 1). The nerve activity consisted of brief bursts of between one and 150 action potentials which had a frequency of 300–500 pulses per s. Modally, the drug-initiated activity (DIA) consisted of 10–25 potentials and was complete within 3 s of injection. Dibutyl cyclic AMP in doses up to $800 \mu\text{g kg}^{-1}$ had no effect on denervated muscle (Fig. 1).

Cyclic AMP in doses up to $800 \mu\text{g kg}^{-1}$ or sodium butyrate or 5'AMP in doses up to 1 mg kg^{-1} had no effect on innervated or denervated preparations. Dibutyl cyclic GMP in doses of $1\text{--}2,000 \mu\text{g kg}^{-1}$ had no effect on innervated or denervated preparations and when given before or after the injection of db cyclic AMP, it did not affect the response to the latter nucleotide.

NaF produced responses which were qualitatively the same as those of db cyclic AMP (Fig. 2), causing SBR and DIA in motor axons, and potentiating the strength of indirectly evoked muscle contractions and causing asynchronous muscle contractions in unstimulated preparations. The threshold dose was $50 \mu\text{g kg}^{-1}$ and a ceiling of effect occurred at $400 \mu\text{g kg}^{-1}$. Injections of NaF up to $800 \mu\text{g kg}^{-1}$ had no effect on denervated muscle.

Theophylline caused SBR in motor axons and potentiation of muscle contraction strength (Fig. 3). The threshold dose was about $100 \mu\text{g kg}^{-1}$ and maximal effect occurred with doses of about $600 \mu\text{g kg}^{-1}$. The effect did not occur as rapidly as after db cyclic AMP or NaF; in most cases

5–10 s elapsed. The repetitive potentials were low in frequency, below 300 Hz, and the trains lasted up to 25 ms (Fig. 3).

Theophylline also produced DIA in nerves and muscles but the dose required was larger than that needed to produce SBR. The activity differed from that initiated by db cyclic AMP and NaF in that there was a delay of several seconds between the injection of the drug and the appearance of the first potentials, and DIA was absent or much less intense if the stimulator was turned off for several minutes before injection. Theophylline had no effect on chronically denervated muscle.

Pretreatment with doses of theophylline below threshold for overt effects (such as $50 \mu\text{g kg}^{-1}$) lowered the threshold dose of db cyclic AMP or NaF by a factor of about 5. Theophylline also greatly increased the intensity and duration of all effects of db cyclic AMP or NaF.

There are several possible mechanisms responsible for SBR in motor axons but prolongation of the afternegativity of an action potential evoked in the nerve terminal is essential to them all^{1,9}. The prolonged afternegativity re-excites a faster recovering proximal segment of the axon (for example, the last node of Ranvier) and thereby produces SBR. Thus, in our experimental conditions, the production of SBR in the axon and/or potentiated contractions in its muscles shows that a reagent reacted with the nerve ending to prolong its afternegativity.

The lack of effect of each compound on chronically denervated muscle suggests that they do not cause a significant direct depolarisation of the post-junctional cell. This is substantiated by the reports that the compounds did not affect muscle membrane potential or amplitude of miniature end plate potentials (m.e.p.p.s) of nerve-muscle preparations. In the absence of significant

Fig. 3 *a*, SBR produced in a soleus motor axon by theophylline. The first trace shows the response to a single stimulus applied before the drug. Subsequent traces show the responses to similar stimuli applied at the given time intervals after intra-arterial administration of theophylline $100 \mu\text{g kg}^{-1}$. Time mark represents 5 ms. *b*, Effects of intra-arterial theophylline (arrows) on the force of contraction of the soleus muscle. The first two records represent the effects of 100 and $400 \mu\text{g kg}^{-1}$, respectively, on a neurally stimulated preparation. The third record represents the effect of $400 \mu\text{g kg}^{-1}$ on chronically denervated muscle.

postjunctional depolarisation, the most likely explanation for the production of DIA is that db cyclic AMP or NaF caused the nerve ending to become sufficiently depolarised to trigger action potentials in the axon and to release transmitter. Theophylline similarly seemed to cause depolarisation of nerve endings, but seemed to require prior activation of the nerve.

As cyclic AMP had no effect in our preparation and as its most significant difference from db cyclic AMP is in the capacity to penetrate cells, our results suggest that dibutyl cyclic AMP acts intracellularly to cause depolarisation of the nerve membrane. Dibutyl cyclic GMP, which also enters cells, also had no effect, suggesting that the effect is not a nonspecific response to intracellular nucleotides. Cyclic nucleotides have been shown to facilitate the influx of Na and/or Ca into cells¹⁰⁻¹⁴, and this can carry depolarising currents and trigger the release of transmitter¹⁵. These observations thus suggest that an increase in the influx of Na and/or Ca could have been the basis for the effects of dibutyl cyclic AMP in our experiments.

The similarity of the effects of NaF, an activator of adenylate cyclase, and dibutyl cyclic AMP, suggests that this enzyme, an important component of cyclic nucleotide systems, is present in motor nerve endings.

Because theophylline induces SBR in motor axons and potentiates and prolongs the effects of db cyclic AMP, phosphodiesterase is likely to be present in the nerve ending. The potentiation and prolongation of the effects of NaF by theophylline suggests that phosphodiesterase participates in the destruction of cyclic nucleotide formed after activation of adenylate cyclase in nerve endings.

If a cyclic nucleotide system was a link between the nerve action potential and transmitter release, it should have four characteristics. First, it should be quiescent until it is activated. Second, it should normally be activated by a nerve action potential. Third, it should be turned on, run its course and be turned off in a few ms. Fourth, it should be modified by exogenous cyclic nucleotides and reagents that affect the enzymes of the cyclic nucleotide system. Our results are in accord with these expectations and suggest mechanisms by which cyclic AMP might participate in neuromuscular transmission.

Release and metabolism of substance P in rat hypothalamus

THE isolation and characterisation of the undecapeptide substance P from extracts of central nervous tissue has promoted renewed interest in the function of this compound in the central nervous system (CNS)¹. In addition, the development of a sensitive and specific radioimmunoassay² and complementary immunohistochemical techniques³ has provided evidence for a differential distribution of substance P in the CNS^{4,5}. Application of substance P to the spinal cord of neonatal rats has been shown to produce a potent depolarising action on motoneurons⁶. Elsewhere in the CNS iontophoretic application of substance P elicits a characteristic neuronal excitation which although slow in onset is long lasting⁷⁻¹⁰. If substance P is to be considered as a neurotransmitter in the CNS, demonstration of its release from nerve terminals in response to physiological depolarisation is the next essential prerequisite¹¹. We have therefore studied the release of substance P from rat hypothalamus, and have

Fig. 1 Release of substance P-like immunoreactivity from rat hypothalamus slices. Adult male Wistar rats (200-250 g) were killed by decapitation, the brains were removed immediately and the hypothalamus was dissected using a modification of the method of Glowinski and Iversen²² (mean wet weight: 45.5 ± 2.1 mg; $n = 10$). Two hypothalami were used in each experiment, chopped in two directions at 0.2-mm intervals and transferred to a Perspex perfusion chamber. The slices were then superfused at 37 °C with Krebs-bicarbonate solution with glucose and containing 0.5% bovine serum albumin at a rate of 200 μ l min⁻¹. The superfusate was collected at 2-min intervals and stored on ice. Twelve minutes after the onset of perfusion, the potassium concentration of the medium was raised to 47 mM for 4 min (horizontal bar). In some experiments, the calcium concentration of the superfusion medium was reduced to 0.1 mM and the magnesium concentration raised to 3.5 mM. Samples of 200 μ l of serial superfusate fractions were removed for determination of substance P-like immunoreactivity by radioimmunoassay. Hypothalamic slices recovered after the superfusion were extracted and substance P-like immunoreactivity is expressed as a fractional rate constant, which represents the amount released per minute in each sample as a percentage of the total tissue content of peptide. Each point is the mean \pm s.e.m. for five experiments. ● Normal medium; ○, low Ca²⁺ medium.

demonstrated a potassium-evoked and calcium-dependent release of immunoreactive material. In addition preliminary results suggest that metabolic degradation rather than tissue uptake is responsible for the inactivation of substance P after its release from brain tissue.

Throughout this study substance P was measured by a radioimmunoassay, essentially similar to published methods². The lower limit of sensitivity was approximately 10 pg of substance P per assay sample. Antibody specificity was checked against the related peptide eleodoisin (Sigma), which failed to cross react with substance P even when present in 1,000-fold molar excess.

Using this radioimmunoassay procedure, we have found that rat hypothalamus contains a relatively high concentration of substance P-like immunoreactivity (SPLI)¹², in agreement with previous results in human brain¹. Rat hypothalamus was, therefore, chosen as a suitable tissue for release studies². A selective, calcium-dependent release of neurotransmitter candidates both *in vivo* and *in vitro* can be induced by raising the potassium concentration in the release studies². A selective, calcium-dependent release of neurotransmitter candidates both *in vivo* and *in vitro* can be induced by raising the potassium concentration in the external medium^{13,14}. Accordingly, to study the release of SPLI, rat hypothalamic slices were continuously superfused with Krebs-bicarbonate solution as described previously¹⁵, and potassium-evoked release was monitored. In

Fig. 2 Metabolism of substance P in rat hypothalamic slices. Portions (10 mg) of a suspension of rat hypothalamic slices were incubated in 1 ml of Krebs-bicarbonate solution with added glucose containing 0.5% bovine serum albumin at 37 °C for various times. At the end of incubation, samples were stored on ice and centrifuged at 1,500g for 10 min, and both supernatant and tissue were assayed for substance P-like immunoreactivity. Each point is the mean \pm s.e.m. for at least six determinations.

preliminary experiments the recovery of internal standards of substance P added to tissue extracts or superfusate samples was more than 94%. To prevent absorption of substance P to the apparatus and collection tubes, bovine serum albumin (0.5% w/v) was routinely added to the superfusion medium. Elevation of the potassium concentration in the superfusing medium to 47 mM for 4 min resulted in a marked increase in the rate of release of SPLI (Fig. 1). The maximum increase in release occurred within 4 min of potassium application, and efflux returned to spontaneous levels 6 min after restoration of normal potassium concentrations. Superfusion of hypothalamic slices with a medium in which the calcium concentration had been reduced to 0.1 mM and the magnesium concentration raised to 3.5 mM did not significantly affect the spontaneous efflux.

The marked increase in release evoked by 47 mM potassium, however, was completely abolished in the low Ca^{2+} and high Mg^{2+} medium. Potassium-evoked release of SPLI from rat hypothalamic tissue therefore seems to

be highly calcium dependent, as is the case with other neurotransmitter release mechanisms. SPLI remaining in the tissue at the end of each release experiment was determined. After 30 min of superfusion with normal Ca^{2+} medium, including 4 min of potassium stimulation, hypothalamic slices contained $663 \pm 50 \text{ ng g}^{-1}$ (mean \pm s.e., $n = 5$), a value not significantly different from that in freshly prepared slices not subjected to superfusion ($745 \pm 40 \text{ ng g}^{-1}$; $n = 6$) or in slices superfused with the low Ca^{2+} /high Mg^{2+} medium for 30 min ($637 \pm 86 \text{ ng g}^{-1}$; $n = 5$). The mean rate of spontaneous efflux of SPLI in normal or modified medium was equivalent to a total release of 8–10% of the tissue content during 30 min. The apparently small pool of tissue substance P available for release, and the high degree of retention of the peptide in the tissue, are similar to the results obtained with other transmitter substances in this type of release experiment^{14,15}.

If substance P is released as a neurotransmitter, mechanisms for inactivating the free peptide might be expected to exist in nervous tissue. To examine this possibility, we incubated hypothalamic slices in Krebs-bicarbonate medium at 37 °C for various times up to 60 min, without superfusion. Figure 2 shows that the rate of decline of SPLI in the hypothalamic tissue was slow: levels after 30 min were 89% of those at the onset of incubation. This figure is in good agreement with the values found in release experiments. In the absence of superfusion, however, no free peptide was detectable in the incubation medium at any time. After 60 min of incubation it was still not possible to detect SPLI in the incubation medium, although at this time tissue levels had fallen to 57% of the original values. It seems possible therefore that although tissue stores of substance P are reasonably stable, liberated substance P is susceptible to degradation within the hypothalamic tissue. Incubation of synthetic substance P with rat brain homogenates has been shown to result in rapid inactivation, with the release of all constituent amino acids¹⁶. In the release studies reported above, the continuous superfusion procedure presumably reduced such inactivation.

The possibility that the released peptide might be inactivated by a tissue uptake mechanism was also investigated in the rat cerebral cortex, dorsal and ventral spinal cord, substantia nigra, hypothalamus and cerebellum. Slices of these tissues (0.2 mm \times 0.2 mm) were incubated with ^{125}I -N¹-tyrosyl-substance P in the concentration range 10^{-7} – 10^{-6} M at 0, 25 and 37 °C. In no case did tissue: medium ratios significantly exceed unity, even with incubations of up to 40 min duration. Incubation of rat hypothalamic slices with unlabelled synthetic substance P at the same concentrations also failed to demonstrate any accumulation of the peptide. It seems unlikely, therefore, that substance P is actively accumulated by the tissue from which it is released.

Our results demonstrate that endogenous SPLI can be released from rat hypothalamic tissue in response to a depolarising stimulus by a calcium-dependent mechanism. Although the cellular origin of the released peptide is not known, it seems likely that release occurs from substance P-containing nerve terminals in the hypothalamus. Previous biochemical studies have shown that most of the substance P in homogenates of brain¹⁷ and hypothalamus¹⁸ is localised in synaptosome particles. Furthermore, immunohistochemical findings suggest that most of the SPLI in rat hypothalamus is concentrated in nerve terminals⁴. Our results also agree with those of earlier studies which showed the presence of substance P-like activity in the superfusates collected from spinal cord¹⁹ and cerebral cortex²⁰, although these studies were performed before the advent of the specific and sensitive radioimmunoassay procedure. There

have also been preliminary reports of a stimulus-evoked release of SPLI from rat spinal cord^{11,21}.

The above demonstration of release adds further weight to the hypothesis that substance P serves a neurotransmitter role in the nervous system. Although more information is needed on possible mechanisms of inactivation, our results suggest that tissue metabolism rather than a re-uptake mechanism is the important pathway for terminating the actions of the released peptide.

T.J. is in receipt of a MRC studentship and I.K. is a fellow of the Wellcome Trust. We thank Dr D. Powell, Endocrine Unit, Mater Hospital, Dublin for demonstration of radioimmunoassay methods and Dr J. S. Kelly for reading the manuscript. Synthetic substance P used was obtained from Beckman Instruments Inc. and the Protein Research Foundation, Osaka, Japan.

Release of substance P-like immunoreactivity from isolated spinal cord of newborn rat

EVIDENCE is accumulating that substance P (H-Arg-Pro-Lys-Pro-Gln-Gln-Phe-Phe-Gly-Leu-Met-NH₂)¹ is an excitatory transmitter released from primary afferent nerve terminals in mammalian spinal cord (for reviews see refs 2 and 3). An important criterion for identification of a transmitter is the demonstration of release of the candidate substance from the nerve terminals in response to presynaptic stimulation. We report here the release of substance P-like immunoreactivity from isolated rat spinal cord into the bathing fluid during stimulation of dorsal roots.

Spinal cords from the thoracic level to the caudal end of 1-2-d-old Wistar rats were isolated, hemisected sagittally and placed in a 0.3-ml bath⁴. The preparation was perfused with oxygenated Krebs solution at 27 °C to which 6 µM dithiothreitol

was added to protect substance P against oxidation. Dithiothreitol at this concentration did not affect spinal reflexes, which indicated that the drug did not interfere with the oxygenation of the spinal cord. In most experiments, either 7 nM pepstatin⁵ or trasylol (0.5 U ml⁻¹) was added to the perfusion fluid to inhibit the degradation of substance P by proteases. Four to six lumbar dorsal roots were placed in suction electrodes for electrical stimulation. One of the ventral roots (L3-L5) was placed in another suction electrode with a tip diameter just fitting the size of the ventral root for extracellular recording, and the reflex responses were monitored during the stimulation periods. The perfusion rate was 0.2-0.6 ml min⁻¹, and after the preparation had been washed for at least 1 h, the perfusate was collected for 15 or 30 min into test tubes which each contained 1 ml of 60 mM dithiothreitol. Samples were frozen immediately, lyophilised and submitted to radioimmunoassay for substance P (ref. 6). The details of the assay system are described elsewhere⁷. Antisera against substance P were raised in rabbits, using synthetic substance P coupled with human α-globulin. ¹²⁵I-N¹-tyrosyl-substance P was used as tracer. The minimum detectable amount of substance P by the assay system was 2.5-5 pg per incubate. The antibody cross reacted with some of the shorter C-terminal analogues of substance P (deca-, nona- and octapeptides) but not with other shorter C-terminal analogues.

Fig. 1 Substance P-like immunoreactivity in the perfusates of isolated spinal cords of newborn rats. Each column represents the immunoreactivity expressed as an amount of substance P in a sample of about 7 ml. Stimulation periods and frequencies are indicated in the figure. The duration of each stimulating pulse was 0.01 ms in (a), and 0.3 ms in (b). In the experiment shown in (b), the preparation was first perfused with normal Krebs solution and then with a Ca²⁺-deficient and Mg²⁺-rich Krebs solution.

Figure 1 shows the results of two typical experiments. In the experiment shown in Fig. 1a, rectangular pulses of 0.01 ms were used for stimulation. During the resting periods, the amounts of substance P-like immunoreactivity in 30-min collection samples were below the limit of accurate measurement. Stimulation of the dorsal roots at a frequency of 5 Hz induced a slight increase, and stimulation at 10 Hz caused a definite increase in the release of substance P-like immunoreactivity. When the preparation was perfused with modified Krebs solution in which K⁺ concentration was increased to 55 mM, a large amount of the immunoreactivity was released into the perfusate. In the experiment illustrated in Fig. 1b, longer stimulation pulses (0.3 ms) were used to activate the smaller fibres in the dorsal roots. During the first stimulation period in normal Krebs solution a remarkable increase of substance P-like immunoreactivity in the perfusate was found, and this was associated with continual reflex responses throughout the stimulation period. But when the preparation was perfused with

modified Krebs solution containing 0.2 mM Ca^{2+} and 7 mM Mg^{2+} , which abolished monosynaptic and polysynaptic reflexes, the same stimulation produced no change in the immunoreactivity in the perfusate. Similar results were obtained when the experimental procedures were reversed; that is another spinal cord was first perfused with the Ca^{2+} -deficient and Mg^{2+} -rich Krebs solution, where the stimulation at 10 Hz for 15 min produced no reflex responses and no significant change of the immunoreactivity in the perfusate; the preparation was then perfused with normal Krebs solution and the same stimulation produced continual reflex responses and a marked increase in substance P-like immunoreactivity.

The results presented here demonstrate the calcium-dependent release of substance P-like immunoreactivity from the isolated rat spinal cord in response to stimulation of dorsal roots. Angelucci⁸ has shown that a substance P-like agent is released from perfused frog's spinal cord, but obtained no clear evidence as to whether its rate of release increased during reflex activity. Jessell *et al.*⁹ demonstrated the potassium-evoked and calcium-dependent release of substance P-like immunoreactivity from rat hypothalamus. The substance P-like immunoreactivity collected in our experiments is likely to have originated from nerve terminals of primary afferent fibres in the spinal cord, because previous studies^{10,11} gave good evidence for the occurrence of substance P in these fibres. Thus our findings support the view that substance P is an excitatory transmitter released from dorsal root fibres.

We thank Professor N. Yanaihara for radioimmunoassay of substance P.

Macromolecules, steroid binding and testosterone secretion by rabbit testes

THE formation of testosterone by the testis has been studied extensively and the general characteristics of the process have been described¹. But the mechanism by which testosterone escapes from the steroidogenic cell and then from the testis is largely unknown². Eik-Nes³ speculated that testosterone secretion could be explained by the presence of plasma constituents which bind the hormone. These plasma constituents might include erythrocytes, albumin and sex-hormone-binding globulin which have association constants for testosterone of 1×10^3 (ref. 4), 3×10^4 (ref. 5) and 1×10^5 (ref. 6), respectively. On the basis of this information, we hypothesised that testosterone secretion is dependent on diffusion from the steroidogenic cell into the blood and that this diffusion is enhanced by the presence of steroid-binding macromolecules in the blood. We report here a test of this hypothesis.

Rabbit testes were perfused *in vitro*⁷⁻⁹ at 10 ml per g of testis per h with medium containing macromolecules

which differed widely in steroid-binding capacity. These initial studies focused on serum albumin for three reasons: (1) its physical, chemical, and steroid-binding characteristics are well known; (2) it is the only steroid-binding protein commercially available in a highly purified but stable form, and (3) its plasma concentration and high capacity for steroids make it a likely candidate for one component of a macromolecular steroid sink in blood.

The medium for control perfusions consisted of Krebs-Ringer bicarbonate buffer, pH 7.4, 3% (w/v) bovine serum albumin (BSA), fraction V (Reheis Chemical Co.), washed bovine erythrocytes (25% in the medium), crystalline penicillin ($1,000 \text{ IU ml}^{-1}$), glucose (100 mg%) and a saturating concentration of NIH-LH-S17, ovine (100 ng ml^{-1}). The medium was gassed with a mixture of air and 5% carbon dioxide. For experimental perfusions, fraction V BSA was omitted and in some cases replaced with 3% 4 \times crystalline BSA (ICN Pharmaceuticals), 3% ovalbumin (Sigma) or 3% Dextran T70 (Pharmacia). Venous effluent from perfused testes was collected at hourly intervals during each experiment. The blood cells were sedimented by centrifugation and washed with an equal volume of 0.9% (w/v) saline. The saline was combined with the plasma portion of the venous effluent and frozen. The testosterone content of this material or of testicular homogenate was measured by gas-liquid chromatography¹⁰.

In vitro binding of testosterone to BSA, ovalbumin and Dextran was determined by equilibrium dialysis, according to Westphal's method¹¹. After dialysis for 18 h at 4 °C, testosterone ($0.5 \mu\text{g ml}^{-1}$) was found to be 86% bound to BSA, whereas it was only 22% bound to ovalbumin and less than 5% bound to Dextran.

In a further series of experiments, one testis from each of 24 rabbits was perfused with medium containing 3% fraction V BSA. The contralateral testes from six of the rabbits were perfused with medium without albumin; six with medium containing 4 \times crystalline albumin; six with medium containing 3% Dextran, and six with medium containing 3% ovalbumin. This experimental design enabled us to compare testosterone secretion by paired testes, thus eliminating the large variance in secretion between animals. Testosterone content of the venous effluent collected during the second hour of a 2-h perfusion was determined as described above.

The 24 testes perfused with medium containing fraction V secreted 17 ± 3.0 (s.e.m.) μg of testosterone per h. The results in Table 1 show that testosterone secretion by testes perfused with medium containing 4 \times crystalline BSA was similar to that obtained by paired testes receiving medium containing fraction V BSA. In contrast, testosterone secretion by testes perfused with medium either devoid of macromolecules or containing Dextran or ovalbumin, was only a quarter of that from testes receiving medium containing fraction V (Table 1).

Table 1 Effect of macromolecular constituents of perfusion medium on testosterone secretion by rabbit testes minus epididymides perfused *in vitro*

Macromolecule	% of Control*
4 \times recrystallised BSA	90 \pm 8.1†
None	26 \pm 3.5
Dextran T70	25 \pm 4.2
Ovalbumin	26 \pm 9.0

Testes were perfused for 2 h.

*Testosterone secretion was determined by measuring the testosterone content of testicular venous effluent collected during the second hour of perfusion and is expressed as a percentage of paired testis control perfused with medium containing fraction V BSA. Each value represents results from six rabbits.

†Standard error of the mean.

Fig. 1 Testosterone secretion by rabbit testes minus epididymides perfused *in vitro* with medium containing either 3% (w/v) fraction V BSA or 3% (w/v) Dextran. ●, Ten testes perfused with medium containing fraction V BSA for 6 h; ○, twenty testes perfused with the medium containing Dextran for the first, second and third hours of a 6-h perfusion experiment; △, ten testes switched to medium containing fraction V BSA during the fourth, fifth and sixth hours of perfusion. The latter ten testes were from the same rabbits that furnished the contralateral testes simultaneously perfused with medium containing fraction V BSA for 6 h. □, ten testes not switched but perfused with medium containing Dextran for 6 h. The \pm above or below each point represents the standard error of the mean.

Substitution of Dextran or ovalbumin for BSA maintains the plasma osmotic pressure, preventing tissue swelling during perfusion. Thus it is unlikely that the diminution in testosterone secretion in the absence of BSA was due to some nonspecific effect on tissue viability. The high rate of secretion by testes perfused with medium containing fraction V BSA was not explained by the presence of a macromolecular contaminant in fraction V BSA since the $4\times$ crystalline BSA, which also supported a high rate of testosterone secretion, gave a single band on gel electrophoresis.

The unlikely possibility that the lipid present in BSA but absent from Dextran served as a substrate for steroidogenesis was eliminated by showing that testosterone secretion was similar in eight testes perfused with medium containing Dextran ($2.9\pm 0.3\ \mu\text{g}$ of testosterone per h), and in eight testes perfused with the same medium plus the residue of a chloroform-methanol extract of an equivalent amount of medium containing 3% fraction V BSA ($2.9\pm 0.4\ \mu\text{g}$ of testosterone per h).

Because these experiments were of short duration, the results could not eliminate the possibility that diminished testosterone secretion in the absence of albumin was only a transient phenomenon, or that reduced testosterone secretion in the absence of albumin resulted from some irreversible change in the steroidogenic cells. We therefore perfused one testis from each of 10 rabbits for 6 h with medium containing 3% fraction V BSA. The contralateral testis from each rabbit was perfused simultaneously with medium containing 3% Dextran for 3 h; then with medium containing 3% fraction V for a further 3 h. Finally, one testis from each of 10 more rabbits was perfused with medium containing Dextran for 6 h. Hourly samples of

venous effluent were collected and testosterone was quantified as described above. Figure 1 shows that testes perfused with medium containing fraction V BSA secreted $19\pm 3\ \mu\text{g}$ of testosterone per h in 6 h. In contrast, testes perfused with artificial medium containing Dextran secreted $4.5\pm 0.7\ \mu\text{g}$ of testosterone per h in 6 h. Importantly, the low testosterone secretion, obtained when testes were perfused with Dextran containing medium for 3 h, returned to the control rate of secretion after being changed to medium containing fraction V BSA (Figure 1). These results show that the low rate of secretion in the presence of Dextran did not increase spontaneously during 6 h of perfusion. Moreover, Dextran did not cause irreversible damage to the testicular steroidogenic cell within 3 h.

It can be calculated from the results in Fig. 1 that testes perfused with medium containing either BSA or Dextran produced $114\ \mu\text{g}$ of testosterone ($19\ \mu\text{g h}^{-1}$ for 6 h) or $27\ \mu\text{g}$ of testosterone ($4.5\ \mu\text{g h}^{-1}$ for 6 h), respectively, during 6 h of perfusion. The testosterone content of testes perfused with medium containing either BSA or Dextran for 6 h was $2.0\pm 0.3\ \mu\text{g}$ and $3.5\pm 0.7\ \mu\text{g}$ of testosterone per testis, respectively. This difference of $1.5\ \mu\text{g}$ in testicular content fails to account for the difference of $87\ \mu\text{g}$ in the amount of testosterone secreted by testes perfused with medium containing BSA, rather than with Dextran. Similarly, the testicular content of 5α androstan- 17β -ol-3-one, 5α androstan- $3\alpha,17\beta$ -diol, 5α androstan $3\beta,17\beta$ -diol and $\Delta 4$ androst- $3,17$ -dione failed to account for significant amounts of the $87\text{-}\mu\text{g}$ discrepancy in testosterone secretion by testes perfused with medium containing Dextran rather than fraction V BSA. Therefore, diminished testosterone secretion in the absence of BSA cannot be explained by a failure of testosterone to be released from the testis or by an intratesticular accumulation of testosterone or some common testosterone metabolites.

These are the first experimental results to confirm Westphal's¹ hypothesis that, "binding proteins facilitate the passage of the (predominantly hydrophobic) steroids through the endothelium of the capillary walls". Further experimentation is required: to determine the relative impact of testosterone binding to erythrocytes, albumin or (sex-hormone-binding) globulin on testosterone secretion; to determine the mechanism by which testosterone binding to blood plasma macromolecules increases testosterone secretion; and finally to determine the effect of experimental treatments which alter either the concentration or steroid binding characteristics of blood plasma macromolecules on testosterone secretion.

We thank the NIAMD for NIH-LH-S₁₇ ovine and D. C. Irby and N. McCall for technical assistance. This work was supported in part by a fellowship, a contract and grants from the NICHD.

Recognition of lysosomal glycosidases *in vivo* inhibited by modified glycoproteins

PURIFIED liver lysosomal glycosidases display very short plasma survival times following intravenous injection. The mechanism by which these hydrolases are cleared from plasma involves specific recognition of the enzymes by way of sites associated with the enzyme molecules. In our study, a modified plasma glycoprotein terminating in *N*-acetyl-glucosamine has been shown to inhibit recognition and clearance of several purified lysosomal glycosidases.

Lysosomal glycosidases are glycoproteins^{1,2} mainly intracellular³ with only trace amounts normally occurring in plasma and extracellular fluids. Recent work⁴⁻⁷ indicates that various highly purified lysosomal glycosidases are very rapidly cleared from the circulation after intravenous administration. Rapid plasma clearance of lysosomal glycosidases seems to be mediated by liver plasma membrane binding sites or receptors⁸ with subsequent endocytosis and incorporation into liver lysosomes⁷. Rapid clearance is not a characteristic of all forms of a given glycosidase since some species (for example, purified normal serum β -glucuronidase)⁷ are not cleared and display relatively long plasma half lives. Moreover, the administration of diisopropylfluorophosphate⁹ rapidly raises the concentration of slow clearance forms of β -glucuronidase in rat plasma.

Extracellular survival of many glycoproteins is determined by the exposed or terminal sugar residues associated with the carbohydrate chains⁹. Nearly all plasma glycoproteins, for instance, having galactose as the penultimate sugar are rapidly cleared from plasma when the terminal sugar (sialic acid) is removed¹⁰. The mechanism of clearance of various asialo-glycoproteins with exposed galactose residues involves binding to a liver parenchymal cell plasma membrane receptor¹¹. More recently, a second clearance route dependent on previous sequential removal of two sugars (sialic acid and galactose) from the carbohydrate chains of orosomucoid, has been described^{12,13}. Enzymatic removal of two sugars from orosomucoid results in the exposure of *N*-acetyl glucosamine. Plasma clearance of agalacto-orosomucoid seems to be mediated by recognition of terminal *N*-acetyl-glucosaminyl residues.

Several lines of evidence suggest that carbohydrate residues are important in mediating the clearance of lysosomal glycosidases¹⁴. In the hope of identifying the recognition site(s) associated with rapidly-cleared glycosidases, clearance competition experiments were undertaken using a family of purified rat liver lysosomal hydrolases including β -glucuronidase, β -galactosidase, *N*-acetyl- β -D-glucosaminidase and α -fucosidase. Asialo-orosomucoid (ASOR) and agalacto-orosomucoid (AGOR) were used as antagonists.

Clearance of various glycosidase activities was followed in the anaesthetised rat after a brief intravenous infusion of enzyme. The enzyme preparations were prepared from rat liver lysosomes and rat preputial gland. Rat preputial gland is an extremely rich source of β -glucuronidase from which large quantities of highly purified enzymes can be isolated. β -Glucuronidase from rat preputial gland and rat liver lysosomes are indistinguishable on the basis of catalytic properties⁷, molecular dimensions^{15,16} and clearance following intravenous infusion⁷.

Rat preputial gland β -glucuronidase, purified by the method of Ohtsuka and Wakabayashi¹⁷ had a specific activity of 2,000 phenolphthalein glucuronic acid (PGA) units mg^{-1} (see Table 1). Liver lysosomal β -glucuronidase, isolated by a modification of the method of Stahl and Touster¹⁸ using an affinity chromatography step described by Owens *et al.*¹⁹, had a specific activity of 1,000 PGA units mg^{-1} . β -Galactosidase was isolated from rat liver lysosomes with subsequent purification on concanavalin A-Sepharose as described by Stahl *et al.*⁷ and *p*-aminophenyl- β -D-thiogalactosyl-Sepharose as described by Distler and Jourdan¹⁹. The preparation used had a specific activity of 50 *p*-nitrophenyl (PNP) units mg^{-1} . α -Fucosidase, from rat liver lysosomes, was purified by affinity chromatography using ξ -amino-caproyl-fucosamine-Sepharose (Fucosylex, Miles). *N*-acetyl- β -D-glucosaminidase was isolated from rat liver lysosomes, as described by Stahl *et al.*⁷, to a specific activity of 880 PNP units mg^{-1} .

Fig. 1 Effect of AGOR on the clearance of liver lysosomal β -glucuronidase, β -galactosidase, and NAGA. Enzyme was infused as described in Table 1 with and without 1.0 mg AGOR. Plasma enzyme levels are expressed, after subtraction of pre-infusion plasma levels, as a percentage of the 1.5-min sample. \circ , β -Glucuronidase; Δ , β -galactosidase; ∇ , *N*-acetyl- β -glucosaminidase; \bullet , β -glucuronidase + AGOR; \blacktriangle , β -galactosidase + AGOR; \blacktriangledown , *N*-acetyl- β -glucosaminidase + AGOR.

All enzymes were administered in 0.15 M NaCl. Asialo-orosomucoid was prepared by digestion of purified orosomucoid with *Clostridium perfringens* neuraminidase. The latter was protease-free. Agalacto-orosomucoid was prepared from asialo-orosomucoid by treating the latter with β -galactosidase isolated from the culture fluid of *Diplococcus pneumoniae*.

Clearance of three liver lysosomal glycosidases, β -glucuronidase, β -galactosidase and *N*-acetyl- β -D-glucosaminidase is summarised in Fig. 1. Two other enzymes, rat preputial β -glucuronidase and liver lysosomal α -fucosidase were also studied (Table 1). Clearance profiles in Fig. 1, constructed from analysis of sequential arterial plasma samples, demonstrate the very rapid nature of enzyme

Table 1 Effect of agalacto-orosomucoid and asialo-orosomucoid on the clearance of various lysosomal hydrolases

Lysosomal (L) β -glucuronidase, 20 PGA units (20 μ g), preputial gland (P) β -glucuronidase, 10 PGA units (5 μ g), β -galactosidase, 5 PNP units (100 μ g), *N*-acetyl- β -D-glucosaminidase, 20 PNP units (22 μ g); and α -L-fucosidase, 5 PNP units (11 μ g) were infused by femoral vein cannula into the anaesthetised rat without (—) or with ASOR (1 mg) or AGOR (1 mg), respectively, in a total volume of 0.5 ml. Female Wistar rats (50–60 g), anaesthetised with sodium pentobarbital (30 mg kg⁻¹, intraperitoneally), were used throughout. Femoral vein and carotid artery cannulations were made and enzyme preparations were infused for 70 s. The first blood sample was taken at 90 s using heparinised haematocrit tubes. Further details are described by Stahl *et al.*⁷. β -Glucuronidase was assayed using PGA¹⁶ or 4-methylumbelliferyl-(MU)-glucuronide as described by Stahl *et al.*⁷. β -Galactosidase was assayed using 2.5 mM PNP- β -D-galactoside or MU- β -D-galactoside. The reaction was run in 0.1 M Na acetate pH 4.3, containing 0.5 M NaCl and terminated by the addition of alkaline stopping reagent¹⁸. *N*-acetyl- β -D-glucosaminidase and α -fucosidase were assayed using the appropriate PNP- and MU-glycosides as described by Stahl *et al.*⁷. All units of enzymatic activity are expressed as μ mol product formed per h. Protein was determined by the Miller method²⁰. The results are the average of two animals per enzyme determination. Results for AGOR (1 mg) infusion are from one animal only. Plasma enzyme levels are expressed as MU units per ml plasma. Preinfusion control plasma enzyme levels have been subtracted from post-infusion values. Plasma half life was estimated as the time required to reach 50% of the 1.5-min plasma level. NAGA = *N*-acetyl- β -D-glucosaminidase.

clearance. The actual plasma enzyme levels at selected post-infusion time points appear in Table 1.

When various lysosomal glycosidases were infused with 1 mg AGOR, the enzyme clearance curves were shifted considerably to the right (Fig. 1). As expected, plasma half life for each enzyme was appreciably extended and plasma enzyme levels 30 min after infusion were enhanced many times (Table 2). Injection of 1 mg AGOR alone (Table 2) had no effect on plasma glycosidase levels. Corresponding experiments were undertaken to determine whether ASOR has any inhibitory effects on enzyme clearance. ASOR (1 mg) had no effect on clearance of the five lysosomal enzyme preparations (Table 2).

To test whether inhibition of clearance of β -glucuronidase is dependent on the concentration of inhibitor, a series of doses of AGOR were administered with a tracer dose (0.005 mg) of preputial β -glucuronidase. The rate of enzyme clearance was measured as described previously⁷. Briefly, for each dose of AGOR, a semi-log plot was made of plasma enzyme level against time. The initial enzyme clearance rate was estimated from the slope of a line drawn through the first few (2–4) time points. Clearance rates,

expressed as units ml⁻¹ min⁻¹, are summarised in Table 2 for a series of doses of AGOR. As little as 30 μ g of AGOR reduced β -glucuronidase clearance by 25%. The dose-dependent nature of AGOR inhibition of preputial β -glucuronidase clearance suggests that the two are competing for the same receptor site. However, this point will require more kinetic and structural analysis.

Previous work from our laboratory¹⁴ with two rat lysosomal glycosidases, β -glucuronidase and *N*-acetyl- β -D-glucosaminidase, indicated that periodate oxidation of the enzymes resulted in loss of rapid clearance without appreciable changes in catalytic activity. These results, along with those of Hickman *et al.*²¹, suggest that sugar residues are important in enzyme recognition and uptake by cells. The observations reported in the present paper where an *N*-acetyl-glucosaminyl terminal glycoprotein inhibited clearance of a family of lysosomal glycosidases support and extend earlier work implicating carbohydrate residues in the recognition site. Further, the results suggest that the recognition site includes *N*-acetyl glucosamine. Confirmation of this must await chemical analysis of glycopeptides derived from lysosomal enzymes. Of considerable interest are the recent findings of Achord, Brot, Gonzales-Noriega and Sly (in preparation), that highly purified human placental β -glucuronidase is rapidly cleared from the circulation in the rat and that the clearance system seems to recognise the carbohydrate moiety of the enzyme. Our results would suggest that the liver recognition system, described in mammals by Stockert *et al.*²² and in birds by Lunney and Ashwell¹³ and Regoeczi *et al.*²³ for modified glycoproteins, may function to maintain the very low levels of lysosomal enzymes found in extracellular fluids. The results may prove to be important in enzyme replacement therapy for lysosomal enzyme deficiency storage diseases.

This work was supported by grants from the NIH. P.H.S. was supported through an NIGMS Medical Genetics training grant. We thank Drs D. Achord and W. S. Sly particularly for providing us with data on clearance of

Table 2 Effect of agalacto-orosomucoid on β -glucuronidase clearance rate

Enzyme (units)	Inhibitor (mg)	β -Glucuronidase clearance rate (units ml ⁻¹ min ⁻¹)
β -Glucuronidase (10)	—	0.55
	AGOR (0.03)	0.32
	AGOR (0.1)	0.30
	AGOR (1.0)	0.21

The effect of AGOR on the initial plasma clearance rate of preputial β -glucuronidase (10 PGA units) was estimated by plotting plasma enzyme levels after termination of infusion, as described in Table 1, against time. The rate was calculated from the slope of a line connecting the first few (2–4) points on the clearance curve as described in ref. 7. Various amounts of AGOR were added to the infusate.

human β -glucuronidase before publication. We also thank Dr Gilbert Ashwell, for providing ASOR and AGOR and for helpful suggestions, and Dr Oscar Touster, Department of Molecular Biology, Vanderbilt University, Nashville, Tennessee (Opheim and Touster, in preparation), for providing the method of purifying α -fucosidase.

Model for the structure of the gastric mucous gel

THE surface of the stomach is covered by a layer of mucous gel which protects the underlying mucosa from the harmful, acidic stomach contents. The principal component of the gel has been isolated from pig gastric mucus, purified, and shown to be a glycoprotein of molecular weight 2×10^6 (Table 1)^{1,2}. This glycoprotein consists of four equal sized subunits (molecular weight 5×10^5) joined by disulphide bridges^{3,4}. Each glycoprotein subunit consists of a protein core, 14% by weight of the glycoprotein, with carbohydrate side chains attached. The protein core consists of two regions, one rich in serine, threonine and proline and bearing all the carbohydrate, the other having an amino acid composition characteristic of a globular protein. The latter contains cystine residues which bridge the four subunits. Mild reducing agents and proteolytic enzymes each split the glycoprotein into four subunits^{4,5}. The carbohydrate chains, approximately 15 residues in a branched structure, account for 82% by weight of the glycoprotein and carry ester sulphate residues. The problem therefore is to explain how such a glycoprotein molecule can associate to form a gel which *in vivo* is essentially impermeable to proteolytic enzymes and which can act as a barrier to protons probably by supporting a pH gradient.

The mucous gel isolated directly from the stomach is clearly viscoelastic, despite its non-uniform concentration. It can be completely solubilised by guanidinium chloride or by, homogenisation in water, demonstrating that the gel is stabilised solely by non-covalent interactions between the component glycoprotein molecules⁶. The solubilised gastric glycoprotein, in 0.2 M KCl, has a high intrinsic viscosity of 320 ml g⁻¹ but

Fig. 1 The dependence of the viscosity of the gastric glycoprotein on concentration: plot of $\log \eta_{sp}/c$ against $\log c$. Viscosities were measured using a Couette viscometer. Solvent: 0.2 M KCl, 0.02% (w/v) azide; 0.02 M K acetate buffer, pH 5.5.

the concentration dependence of its viscous, sedimentation and diffusion properties indicate a surprisingly low degree of intermolecular interaction (see Table 1) (Fig. 1). At higher glycoprotein concentrations of 20–30 mg ml⁻¹ the viscosity indicates a deviation from this behaviour and intermolecular interaction assumes an increasingly significant contribution to the viscosity of the solution. This is demonstrated by the logarithmic plot of reduced specific viscosity against concentration (Fig. 1), where the increase in slope on going from low to higher concentrations of glycoprotein is characteristic of the behaviour of certain interacting synthetic polymers⁷. The major change in behaviour occurs in the concentration range 20–25 mg ml⁻¹. Concentrating the glycoprotein further will result in gel formation *in vitro*, although the nature of this gel and the exact conditions for its formation have yet to be studied in detail. The average concentration of the glycoprotein found in mucous gel isolated directly from the stomach is in the region of 30–40 mg ml⁻¹, that is, in the range in which intermolecular interaction is shown above to be occurring.

The flow properties of the glycoprotein at low concentrations in 0.2 M KCl solution can be accounted for by a molecule which is highly expanded and approximately spherical⁸. An indication of the solution volume occupied by the glycoprotein at high dilution is given by its effective hydrodynamic volume, V_e , from the relationship

$$V_e = (f/6\pi\eta_0)^3(4\pi\mathcal{N}/3M)$$

assuming the molecule is spherical. f is the frictional coefficient calculated from the diffusion coefficient, η_0 is the viscosity of the solvent, \mathcal{N} is Avogadro's number and M the molecular weight. For the glycoprotein in 0.2 M KCl, V_e has a value of 40 ml g⁻¹. V_e does not define the precise geometry of the molecule itself⁸ but it does give an indication of the volume within which the probability of intermolecular interaction becomes appreciable. On this basis, therefore, the sphere of interaction of glycoprotein molecules will spread over the total solution volume at a solute concentration of 25 mg ml⁻¹. This, it will be noted, is in the concentration range at which independent experimental data shows intermolecular interaction to become significant (Fig. 1). A large volume of solvent is thus enclosed by the glycoprotein molecule and it is quite possible therefore to account for the existence of solutions of concentration higher than 25 mg ml⁻¹ by an overlap of molecular volumes or interdigitation. This would, however, reduce the

Table 1 Properties of the glycoprotein from pig gastric mucus

Sugars were analysed by gas-liquid chromatography and the protein is a summation of the contents of the individual amino acids.

rotational relaxation of the molecule, lead to a rapid rise in viscosity and, at some point depending on the nature and strength of non-covalent intermolecular forces, to gel formation. This point is further supported by calculations of the maximum volume which could be occupied by the glycosylated part (< 90% by weight) of the molecule assuming fully extended sugar chains eight residues in length⁹ forming a cylinder on four extended glycosylated polypeptide chains each 565 residues long. This model leads to a volume of 12 ml g⁻¹ which is a substantial proportion of the effective hydrodynamic volume V_e . The shortfall between this value and that of 40 ml g⁻¹ found experimentally suggests that the four glycoprotein subunits may be flexible about the non-glycosylated disulphide bonded regions of the polypeptide chains.

Based on the above evidence we propose the following model for the structure of the gastric mucous gel. The gel is composed of highly expanded, solution-filling, glycoprotein molecules which, packed together, interact at or near their surfaces. A large proportion of the solvent is thus intramolecular and the polymer extends more or less evenly throughout the gel. This model contrasts with those structures elucidated for other polysaccharide gels such as agar¹⁰ where a much lower concentration of solute can form a relatively low density open network of molecular fibres. The gastric mucous gel, therefore, would be expected to be relatively impermeable to large molecules such as enzymes compared with the free diffusion of such through agar gels. Further, such a structure should reduce considerably any turbulence in the solvent within the gel allowing a relatively stable gradient of pH to be maintained at the surface of the stomach.

This model predicts that gel formation at a given concentration should be markedly dependent on the effective volume in solution of the glycoprotein molecule. Factors such as ionic strength which have been shown to change the size of V_e do in fact markedly affect the intermolecular interactions⁸. It is not yet clear what could stimulate intermolecular interaction between polar chemical groups which appear to be strongly solvated, although there is evidence that removal of water from such structures brings about preferential interaction between sugar chains¹⁰.

Cloning of all *EcoRI* fragments from phage λ in *E. coli*

CLONING of DNA fragments is a new powerful technique in molecular genetics and a number of interesting experiments involving both prokaryotic and eukaryotic genomes have already been reported (see ref. 1 for review). We present here results concerning the cloning of all *EcoRI* (ref. 2) fragments from phage λ DNA in *Escherichia coli* using as a vector plasmid pSC101 (ref. 3). To achieve this, we had to solve the problem of propagating the λ fragment containing the immunity region since the phage strain used had a temperature-sensitive mutation in that region.

DNA from the lysogenising strain c1857 of phage λ and the supercoiled form of plasmid pSC101, were digested at 37°C with restriction enzyme *EcoRI* (prepared according to a modification of the method of Yoshimori⁴) in 100 mM Tris, pH 7.5, and 10 mM MgCl₂ (ref. 5). After digestion was complete, as judged by electrophoresis of the DNAs, *EcoRI* was inactivated by heating the incubation mixtures at 65°C for 5 min. The two digests were then mixed together, slowly chilled to 0°C to allow reannealing of the "sticky ends" formed by *EcoRI* to occur and incubated for 16 h at 0°C and 1 h at 14°C in 50 mM Tris, pH 7.5, 10 mM MgCl₂, 1 mM EDTA, 0.035 mM ATP, 10 mM dithiothreitol⁶ and polynucleotide ligase from T4-infected *E. coli* (from Miles or from Dr F. Rougeon). The ligated mixture was used to transform strain HB 101 (ref. 7) of *E. coli*. The transformants were plated on L agar⁸ containing 15 (or 10, ref. 9) $\mu\text{g ml}^{-1}$ tetracycline, grown overnight at 37°C and further purified on plates containing tetracycline. Selection of recombinant clones was carried out either by a group screening using gel electrophoresis, or by the hybridisation technique of Grunstein and Hogness¹¹.

In an experiment, in which 85 clones were screened in groups of 7-8, at least 10 were found to contain λ fragments 3, 4 or 5 (the numbering of the six *EcoRI* λ fragments is according to decreasing molecular weight¹¹);

Fig. 1. Electrophoresis of recombinant pSC101- λ fragment plasmids before (a) and after (b) *EcoRI* digestion. a, Slots contain: 1, supercoiled circular pSC101; 2, pSC101 + fragment 2 (two copies); 3, pSC101 + fragments 3+5; 4, pSC101 + fragments 1+6; 4a, *EcoRI* fragments of λ DNA; 5, pSC101 + fragment 2; 6, pSC101 + fragment 3; 7, pSC101 + fragment 4; 8, pSC101 + fragment 5. b, Slots 1-8 contain the same plasmids as in a after digestion with *EcoRI*; slots 3a and 6a contain *EcoRI* digests of λ DNA; in slot 3a fragments were heated for 5 min at 70 °C to show the separation of fragments 1 and 6, which gives a single band in non-heated *EcoRI* fragments (slot 6a).

these range in molecular weight from 3.5 to 3×10^6 . One additional clone contained two λ fragments, 3 and 5, which are non-adjacent in the genome and account together for 6.5×10^6 of DNA. Still another clone contained fragments 1 and 6; these fragments are bound together through the natural cohesive ends of λ DNA; they contain the whole left arm of the genome and have a molecular weight of 16×10^6 ; obviously, these fragments cannot be inserted separately since each one of them lacks an *EcoRI* sticky end in the linear form of λ DNA. The easier integration of low molecular weight compared to high molecular weight fragments is expected; our failure to find recombinants harbouring λ fragment 2, which has a molecular weight of 4×10^6 , was, therefore, at first sight, surprising.

An experiment in which λ fragment 2 was eluted from Agarose¹², ligated with pSC101 and used for transfection, did not yield any recombinant plasmid, in spite of the fact that 600 colonies were examined by the hybridisation technique; in contrast, a parallel experiment with fragments 3 and 4 was successful; this suggests that our negative results with fragment 2 were not due to the fact that fragments eluted from Agarose cannot be ligated.

Since fragment 2 comprises the λ immunity region, which is the locus of the temperature-sensitive mutation that induces the lysogen at 37 °C, an experiment was carried out in which Agarose-eluted fragment 2 was ligated to pSC101 and transfectants were grown overnight at the permissive temperature of 30 °C. In this case, 4 out of 600 transfectants were found to be positive by the hybridisation test. The plasmids prepared from three colonies contained a single copy of fragment 2, whereas the fourth clone contained two copies of this fragment.

It may be interesting to remark that recombinant plasmids containing λ fragments may themselves be useful in that they represent new vectors carrying restriction sites brought in by the λ fragments which may not exist in the parent plasmids.

Figure 1 presents the gel electrophoresis results obtained with the recombinant plasmids described above, before and after *EcoRI* digestion.

These experiments were carried out in low-risk containment conditions, as defined by the Asilomar guidelines. All the clones described in the present paper are available on request.

We thank Drs Ken and Noreen Murray for having suggested the experiment of transfectant growth at the permissive temperature.

Azide-dependent mutants in *E. coli* K12

SODIUM azide is known specifically to inhibit or activate a number of enzymatic activities from bacteria¹ and from higher organisms^{2,3}. Furthermore it has been shown that azide can inhibit the Mg^{2+} -dependent ATPase of *Escherichia*

Table 1 Classification of *E. coli* mutants

	I (ADA)	II (ADB)	III (ADC)	IV (ADD)
Number of mutants	1	1	3	3
Azide replaced by	Nothing	Nothing	Threonine or pyridoxine	Phenylalanine, tyrosine and tryptophan*
Location of the mutation (Taylor's map)	Around 7 min†	Around 20 min†	0 min- <i>thrC</i>	Around 5 min†

The parental strain is CSH 57A (ref. 6). Ultraviolet mutagenesis (10^{-2} – 10^{-3} survival) was used.

*The parental strain is Trp⁻. The conditional requirement for all three aromatic amino acids was tested on an ADD mutant which received the wild-type *trp* operon by transduction.

†Approximate mapping determined by interrupted conjugation.

*coli in vivo*⁴, at concentrations that do not produce any deleterious uncoupling effects on the membrane energy-transducing apparatus of the cell⁵. We felt that those facts could provide the basis for searching out a new type of mutation in *E. coli*—azide dependency.

The selection procedure involved penicillin treatment in a liquid minimal medium devoid of azide, followed by a second enrichment step given by the presumed slower growth of the mutants on a solid minimal medium containing 2×10^{-3} M azide. Eight independent mutants were isolated and separated into four classes according to the specific replacement of azide for growth and the location of the mutation on the *E. coli* chromosome (Table 1).

Two of the mutants (ADA 1 and ADB 1) have an absolute requirement for azide. Although they exhibit an identical phenotype, conjugation experiments show that they have distinct locations, mapping at about 7 and 20 min respectively on the *E. coli* chromosome. The ADA 1 mutation was shown to be recessive to the wild-type allele. If exponential cultures from either mutant strain were transferred in growth medium devoid of azide all growth ceased in about two hours. Measurements of the kinetics of incorporation of tritiated uracil and ¹⁴C-L-tryptophan in TCA

insoluble material *in vivo* suggest a translational defect in both mutants.

The third class of mutants (ADC 1–3) includes Thr⁻ conditional mutants whose specific requirement for threonine can be replaced either by sodium azide or pyridoxine (Table 1). Mutations were cotransducible at high frequency with *pyrA* and *serB*, and thus presumably mapped in the threonine operon. This was confirmed by the use of a λ phage carrying the entire threonine operon⁷ and three derived λ phages each carrying a mutation in one of the three genes (*thrA*, or *thrB* or *thrC*)⁸: the ADC mutations tested were recessive and mapped precisely in the C gene of the operon Threonine synthase—the C gene product—was then measured in crude extracts from one mutant strain grown on minimal medium containing azide (Table 2). Only 5% of the wild-type specific activity was found in this mutant. The mutant enzymatic activity *in vitro* was not stimulated by sodium azide; on the contrary azide gave a 15–20% inhibition, comparable to the inhibition obtained on the wild-type activity. Kinetics of irreversible thermal denaturation of the enzyme in crude extracts showed monophasic curves for wild-type and mutant activities but with different half lives: about 4.5 min for the wild type and 0.5 min for the mutant at 56 °C. This thermolability of the mutant enzyme compared with its wild-type counterpart seems to be a real property of the modified enzyme since a mixture of mutant and wild-type extracts showed biphasic kinetics compatible with the mere addition of the two separate kinetics. Interestingly enough, in crude extracts, azide potentialised the irreversible thermal denaturation of the wild-type enzyme, but had no such effect—nor any stabilising effect—on the mutant enzyme (Table 2). Once purified, however, the wild-type enzyme (prepared by B. Burr) showed a complex biphasic curve of denaturation kinetics with no measurable effect of azide. Threonine synthase from the parental and the mutant strains was partially purified and the affinity for pyridoxal-5'-phosphate measured. Estimation of dissociation constants for the coenzyme from Hill plots at $v = V_m/2$ gives a value of 1.2 μ M for the wild-type and 8.5 μ M for the mutant enzyme. Consistently, in the absence of any added pyridoxal-5'-phosphate, about 15% of the wild-type enzyme was found to be in the holo-enzyme form whereas no such form could be detected in the mutant. Sodium azide 2×10^{-3} M or 2×10^{-2} M had no significant effect on the dissociation constant of the mutant enzyme for pyridoxal-5'-phosphate.

The last class behaves as pleiotropic conditional mutants. Their growth is dependent either on sodium azide, or on tyrosine, phenylalanine and tryptophan (Table 1). However, shikimic acid does not allow growth. One mutant (ADD 1) was mapped by interrupted conjugation: the gene involved is approximately at 5 min on Taylor's map. Reversion of the Tyr⁻ or Phe⁻ phenotype in all cases tested (more than 100) gave a pleiotropic reversion with the additional property of large excretion of both tyrosine and phenylalanine (reversion rate of about 10^{-5}). Enzymatic activities of the aromatic pathways were measured in crude extracts of two revertant strains grown on minimal medium in the absence of phenylalanine and tyrosine (in the presence of

Table 2 Thermosensitivity of threonine synthase in ADC 1 crude extract

*Not done.

Bacteria were grown exponentially in minimal medium containing the growth factors of the strains (including isoleucine), glucose 0.4% and sodium azide 2×10^{-3} M. Crude extracts were prepared by sonication of the bacteria previously washed with a potassium phosphate buffer 2×10^{-3} M (pH 7.2). For threonine synthase assay, final concentrations in 0.1 ml of the reaction mixture were: 50 mM N-2-hydroxyethylpiperazine-N'-2-ethane sulphonate adjusted to pH 8 with KOH; 100 mM ammonium sulphate; 0.1 mM pyridoxal-5'-phosphate; 0.24 mg ml⁻¹ bovine serum albumin; and 1.3 mM (0.035 mCi mmol⁻¹) ¹⁴C-L-homoserine phosphate (prepared according to ref. 9). The reaction was carried out at 37 °C for 5–60 min. At the end of the reaction, 5 μ l of KH₂PO₄ 1 M and 0.9 ml of barium bromide (11 mg per ml 90% ethanol) were added, and the precipitated mixture was allowed to stand for 5 min at 4 °C. An aliquot of the supernatant was counted for radioactivity. The radioactivity found in the supernatant at 0 min reaction time was subtracted from the radioactivity measured (this background represents less than 2.5% of the total added radioactivity). At least 90% of the non-precipitating radioactive product was shown to be threonine by chromatography. The specific activity of the wild-type enzyme was 11.7 nmol min⁻¹ mg⁻¹ of proteins.

For thermal denaturation experiments, NaN₃ (or NaCl) was preincubated with the crude extract for 10 min at room temperature.

Table 3 Activities of the biosynthetic pathways of tyrosine and phenylalanine in ADD 1 mutant and two revertant strains

Growth medium	Wild type * †	ADD 1 †	Revertant I from ADD 1 *	Revertant II from ADD 1 *
Prephenate dehydratase	7.5	8.0	12.5	11.0
Prephenate dehydrogenase	23.5	23.5	103.5	288.5
Chorismate mutases	34.0	33.5	100.0	335.5
DAHP synthetases	159.0	195.0	267.5	512.5

Crude extract preparation was as described in legend of Table 2. Buffer was potassium phosphate 2×10^{-2} M (pH 7.2). Prephenate dehydratase and chorismate mutase assays were done according to ref. 14. Prephenate dehydrogenase assay according to ref. 15. DAHP synthetase assay according to ref. 15. Units are $\mu\text{mol per min per mg proteins}$ ($\times 10^3$).

*Bacteria were grown exponentially on 63 minimal medium containing the growth factors of the strains and glucose 0.4%.

†Bacteria were grown exponentially on the above medium containing in addition sodium azide 2×10^{-3} M.

tryptophan) (Table 3) Relative to their wild-type counterparts, prephenate dehydratase activity, an enzyme specific to the phenylalanine pathway, was found to be 2.5 higher in strain I and 1.5 higher in strain II; prephenate dehydrogenase, an enzyme specific to the tyrosine pathway, showed an increase of about 12-fold in strain I and 2.5-fold in strain II, chorismate mutases, specific both for phenylalanine and tyrosine, increased about 10 times in strain I and 2.2 times in strain II. As to DAHP synthetases, the increase in both strains was more than threefold, being due largely (but not exclusively) to the tyrosine-sensitive DAHP synthetase increase. It should be noticed that the above enzymes concern three different operons¹⁰⁻¹². ADD 1 mutant, grown in the presence of NaN₃, similarly showed a significant increase in the above activities compared to the wild type grown in the same conditions (Table 3).

In summary, mutations in at least four different genes can result in azide dependency for growth. None map in the described *azi* gene which is responsible for azide sensitivity^{17,18}. Two genes, at distinct locations, appear to be concerned with the translational mechanism of the cell. No known genes of this type in *E. coli* have the required locations. The third class of mutants map in the *thrC* gene, and the fourth class gives rise to a conditional pleiotropic requirement for tyrosine, phenylalanine and tryptophan which has not been previously described.

Although the precise step or mode of action of sodium azide is still to be found, the search for azide-dependent mutants in *E. coli* seems to be rewarding, having given rise to the discovery of three possible new genes and one new allele of a known gene, and perhaps permitting the detection and study of other new genes and new gene products.

We wish to thank Georges N. Cohen for encouragement and stimulating discussions, A. Képès, P. Truffa-Bachi and I. Saint-Girons. The author is a recipient of a fellowship from the Délégation Générale à la Recherche Scientifique et Technique.

Is proton transfer the initial photochemical process in vision?

THERE has been renewed effort¹ to test the so-called proton transfer hypothesis (PTH)² or hydrogen shift¹ formulation for the initial photochemical step in vision. This hypothesis proposes an alternative to photochemical *cis* to *trans* isomerisation of rhodopsin, while attempting to account for some of the spectral properties of bathorhodopsin (previously called prelumi-rhodopsin), particularly certain low frequency lines at 920, 877 and 856 cm⁻¹. Spectral lines in this region are not unique to the resonance Raman spectrum of bathorhodopsin³, however, for similar spectral absorption has been found with 11-*cis* retinal crystals⁴. The discovery that the batho-intermediate formed by irradiating chicken iodopsin at -195 °C spontaneously reverted to iodopsin at -140 °C by a dark, thermal process⁵, rather than decaying to lumiodopsin, also seemed to require such an alternative hypothesis² (Fig. 1). Although an attempt to demonstrate proton transfer by means of tritium incorporation into the retinylidene chromophore failed², Fransen *et al.* apparently now confirm the PTH by their report¹ of a small, though significant incorporation of deuterium into retinal. Their newer experiments are similar in design to the earlier ones, differing mainly in their use of deuterium rather than tritium and their method of analysis of labelled retinal. The experiments described here bear directly on the proposed PTH and were performed with an analogue of retinal, 5-desmethyl (dm) retinal:

They show that the initial compound produced by irradiating a visual pigment, the batho-intermediate, cannot result from the transfer of a proton from the chromophore to opsin.

5-dm retinal was prepared during a study of the spectral properties of visual pigment analogues⁶. The presence of a chromophore bearing a hydrogen atom, rather than a methyl (CH₃) group, on the 5 position of the ionone ring

Fig. 1 Hypothetical mechanism for photochemical proton transfer followed by thermal *cis* to *trans* isomerisation in a visual pigment. The native or regenerated visual pigment, is represented by structure (I). In the experiments referred to^{1,2}, * represents either deuterium or tritium atoms which have been introduced into opsin by incubation in either deuterated or tritiated water, respectively. After photochemical transformation to the batho-intermediate (II), incorporation of deuterium or tritium into the retinylidene chromophore can occur during either the thermal steps leading to the intermediate (IV), or in the hypothetical thermal return of the batho-pigment to (I). Presumably intermediate III is a short-lived transient.

should preclude the formation of the proposed batho-intermediate¹. In particular, the structure designated as (II) in Fig. 1 is impossible in a pigment containing the 5-dm chromophore.

5-dm retinal was synthesised as described earlier⁶ and then purified by high performance liquid chromatography (HPLC). Individual geometric isomers were isolated by HPLC following the procedure and with separations similar to those reported for the isomers of retinal⁷.

Identification of the 5-dm retinal isomers was based on their photochemical behaviour as well as their order of elution from silica gel, which seemed to be the same as that of *cis* and *trans* retinals. The spectral maxima of the individual 5-dm isomers are given in Table 1.

Table 1 Spectral maxima of all-*trans* and mono-*cis* isomers of 5-dm retinal

	(nm)	(nm)
all- <i>trans</i>	373	268 (0.13)
13- <i>cis</i>	368	268 (0.29)
11- <i>cis</i>	367	268 (0.67)
9- <i>cis</i>	367	273 (0.34)

The values given in parentheses are relative heights of the secondary peaks. For each isomer, the main absorption band is arbitrarily assigned an absorbance of 1.0 at the wavelength of maximum absorption. The solvent was hexane.

Each of the isomers was mixed with a digitonin solution of opsin which had been prepared from frozen cattle retinae⁸. Only the 11-*cis* and 9-*cis* isomers combined, in each case forming a pigment with λ_{max} at 480 nm but at rates approximately 100 times slower than observed with the corresponding isomers of retinal. Complete spectra and other properties of these artificial pigments, called 5-dm rhodopsin (11-*cis*) and 5-dm isorhodopsin (9-*cis*) will be presented elsewhere.

To determine the presence and properties of any intermediates during the photolysis of the 5-dm pigments, I studied the photochemical behaviour of 5-dm isorhodopsin at low temperatures, utilising the absorption vessel designed and built by Yoshizawa and Horiuchi⁹ for work at liquid nitrogen temperatures and above. 5-dm isorhodopsin which had been formed by reacting 9-*cis* 5-dm retinal with a digitonin solution of opsin was mixed thoroughly with twice its volume of glycerol. Measured in a 0.3-cm light path cell at 20 °C, the absorbance of the resulting solution was 0.5 at 480 nm. Figure 2a, curve 1 is the spectrum of 5-dm isorhodopsin at 191 °C. Some unreacted 9-*cis* 5-dm retinal remains as the oxime. Spectra resulting from violet light irradiation of the pigment in glycerol-aqueous glass are

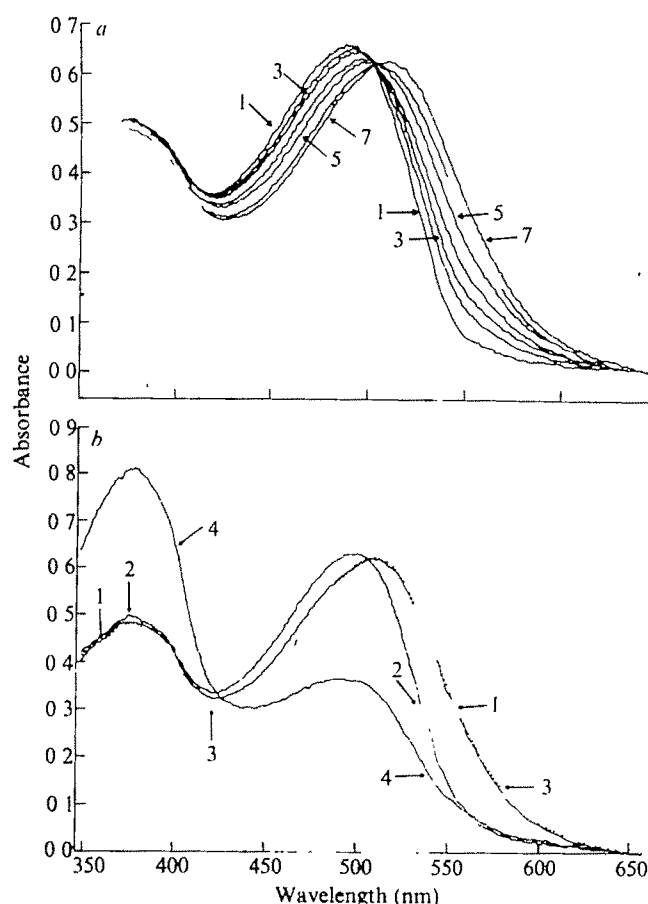

Fig. 2 a, The photochemical transformation of 5-dm isorhodopsin to 5-dm bathorhodopsin. 0.3 ml of a 67% glycerol solution of regenerated 5-dm isorhodopsin in approximately 1% digitonin and 0.01 M NH_4OH , pH 6.5, was placed in a cell with a 3-mm light path. The sample was cooled to -191°C and its spectrum recorded (1). The sample was then illuminated with violet light formed from the radiation of a high intensity xenon lamp which was passed through a 437-nm interference filter. Spectra 2-7 were recorded after total irradiation times of 2 s, 40 s, 80 s, 160 s, 320 s and 1,280 s, respectively. b, The reversible photochemical transformation among 5-dm batho-, 5-dm iso- and 5-dm rhodopsin. Conditions are the same as for a. 1, Same as spectrum (1) in a; 2, after irradiation with red light (600-nm cutoff filter) for 6.5 min; 3, after irradiation of (2) with violet light (437-nm interference filter) for 8 min; 4, after warming solution to $+20^\circ\text{C}$ and then recooling to -191°C .

Fig. 3 Difference spectrum of 5-dm bathorhodopsin at -191°C . Conditions are given in Fig 2a and b. The curve drawn results from subtracting spectral curve (4), from curve (3) in Fig. 2b.

shown in Fig. 2a, curves 2–7. The appearance of an isobestic point at 503 nm argues that Fig. 2a illustrates the single-step transformation of 5-dm isorhodopsin into one, or a mixture of, long-wavelength absorbing intermediate(s).

Photoreversibility of this pigment system is shown in Fig. 2b, first by the transformation of the long wavelength absorbing intermediate(s) into shorter-wavelength-absorbing species, presumably 5-dm rhodopsin and 5-dm isorhodopsin. The first process (curves 1 and 2) is followed by the reformation of the long wavelength absorbing intermediate(s). Thus spectrum 3 of Fig. 2b contains thermostable pigments, presumably 5-dm rhodopsin and 5-dm isorhodopsin, as well as a thermally unstable component which decomposes to 5-dm retinal oxime and opsin when the solution is warmed to 20°C , as shown in spectrum 4. The difference spectrum of the thermally unstable compound, drawn in Fig. 3, has a positive peak with λ_{max} at 525 nm and a band width at half maximum of 95 nm. This spectrum characterises an intermediate which, because of its spectral and thermal analogies to cattle bathorhodopsin⁹, I call 5-dm bathorhodopsin.

When the violet irradiated mixture of 5-dm pigments (Fig. 2b, curve 3), containing 5-dm bathorhodopsin, and presumably 5-dm rhodopsin and 5-dm isorhodopsin, is warmed to only about -165°C , a decrease in absorbance at wavelengths greater than 500 nm and an increase in absorbance in the 400–500 nm region occurs. This change is consistent with the transformation of 5-dm bathorhodopsin into a pigment with λ_{max} at 497 nm and band width at half maximum of 80 nm. I call this pigment 5-dm lumirhodopsin. The spectrum of 5-dm lumirhodopsin and its formation from a longer wavelength precursor at around -165°C suggest it is analogous to cattle lumirhodopsin¹⁰.

These results show that a batho-intermediate can be formed from a pigment lacking an allylic methyl group in the ionone ring of the chromophore. Without such a methyl group it is impossible to transfer a hydrogen atom or ion from a group on the ionone ring to opsin and thereby form the structure proposed^{1,2} for bathorhodopsin. Since 9-dm pigments and 13-dm pigments also form batho-pigments at -190°C (my unpublished results), it seems reasonable to conclude that photochemical proton transfer from an allylic methyl-group on the chromophore to a site on opsin is not responsible for the rhodopsin (or isorhodopsin) to bathorhodopsin transition. *Cis* to *trans* isomerisation

still seems to be the process which can best account¹¹ for the experimental observations bearing on the initial photochemical event in the photochemistry of visual pigments, both natural and artificial.

This work was supported by a grant from the National Eye Institute. The low temperature experimentation was performed while I was a visiting professor in the Department of Biophysics of Kyoto University and I thank Professor T. Yoshizawa and his colleagues for hospitality and assistance. I also thank Professor B. Honig, Hebrew University of Jerusalem, for encouragement and R. B. Kropf for helpful emendations in the manuscript.

Corrigendum

In the article “Perception of melodies” by H. C. Longuet-Higgins (*Nature*, **263**, 646; 1976) there are some errors in the figures. In Fig. 3 the top left-hand number should be -9 ; in Fig. 4 the second x in the left-hand column should be a z ; in Fig. 7 the trilled minim should be prefixed by a $\#$.

Errata

In the article “Male emigration and female transfer in wild mountain gorilla” by A. H. Harcourt *et al.* (*Nature*, **263**, 227; 1976) the second author should be K. J. Stewart and not as printed.

In the article “Axial, magnetron, cyclotron and spin-cyclotron-beat frequencies measured on single electron almost at rest in free space (geonium)” by R. Van Dyck, Jr, P. Ekstrom and H. Dehmelt (*Nature*, **262**, 776; 1976) $(n+\frac{1}{2})\nu_0$ in the first equation should read $(n+\frac{1}{2})(\nu_0-\nu_m)$. In the acknowledgment, for Schwingberg read Schwinberg.

Nature Index and Binders

The **Index** for 1975 is now available, price £2.25. Copies of the 1974 index are still on sale, price £3.00. **Binders** for the journal are also available at £8.00 for four (a year of *Nature* fits into four binders).

Postage is included in the above prices. Orders should be sent, accompanied by remittance to Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire, England.

Secrets of the Earth's core

Thomas H. Jordan

The Earth's Core. (International Geophysics Series.) By J. A. Jacobs. Pp. viii+253 (Academic: New York and London, 1976.) £8.50; \$22.

THE Earth is stubborn in yielding her secrets, and locked most tightly in her depths are the mysteries of her core. The core is separated from us by nearly 3,000 km of rock, so it is no wonder that our papers about its composition, state and dynamics are often prefaced by words like 'assumption', 'hypothesis' and 'paradox'. Pressures within the core are as yet inaccessible by static laboratory apparatus, but fall short of the domain in which the elegant theories of degenerate electron gases may be applied. Nearly everyone agrees that iron and nickel are the dominant atomic species in the core, but further statements about its composition depend heavily on models for the Earth's early history, a subject perhaps still better suited for religious thinkers than natural philosophers. The important questions of core dynamics seem to provide the most secure remaining refuge for the back-of-the-envelope, order-of-magnitude geonomist. For example, the average heat flux across the core-mantle interface is one of the great unknown quantities of terrestrial physics, a number whose demonstrated bounds are virtually useless.

Therefore, few geoscientists would be surprised to learn that, until now, the Earth's core has not been the title subject of a scholarly treatise. This deficiency has been remedied by Professor Jacobs, who has produced a very readable monograph of 253 pages. His narrative sketches the lines of evidence which, when suitably tangled, form the web of our understanding about the core. His treatment of this subject has been divided into five chapters the titles of which outline the content of the book: general physical properties of the Earth, origin of the core; thermal regime of the Earth's core, Earth's magnetic field; constitution of the core. As a bonus he concludes with a sixth chapter on the cores of other planets, paying due homage to the current emphasis on comparative planetology. This last chapter also serves to cheer us up; at least we Earth scientists know

this planet has a core, a conclusion that is uncertain for even the best studied of our neighbours.

The book is comprehensive: space is given to nearly every subject of current interest, although few are treated in any depth. Particularly valuable are the author's discussions of recent attempts to model the physical parameters of the core using seismic methods, his summary of the controversy that has surrounded the so-called Kennedy-Higgins paradox, and his synthesis of the evidence regarding core formation. The chapter on the magnetic field is adequate, although a more thorough treatment of the dynamo problem could have been attempted.

Throughout the book the mathematical level is very elementary, long derivations are absent, and equations are generally used only in a narrative

fashion. In spite of this lack of fancy mathematics, or perhaps because of it, the subject matter is modern and the information content is high. It is a good reference for specialists engaged in core research who wish to know what other specialists are up to. The bibliographies which follow each chapter are excellent, with nearly seven hundred references (including multiple citations), over half of which have been published since 1970.

This book should be an excellent text for graduate courses dealing with the internal constitution of the Earth. It will be interesting to see if, in five or ten years, this is still true. □

Thomas Jordan is Assistant Professor at the Scripps Institution of Oceanography, La Jolla, California.

Introduction to physiological psychology

Brain and Behaviour: A Textbook of Physiological Psychology. By Hugh Brown. Pp. x+413. (Oxford University: New York and London, March 1976.) £9.25.

THIS introduction to physiological psychology has grown out of a series of lectures for undergraduates. The author initially grapples with the problem of providing a balanced grounding in the principles of nervous function and I think he succeeds in his aim of holding the attention of the reader while proceeding at a somewhat breathless gallop through the first half of the book. The text is chatty and is liberally punctuated with anecdotes, photographs and excellent illustrations. Jargon is kept to a minimum and there is a glossary of terms at the end, ranging from ablation and acalculia to Witzelsucht and the Young-Helmholtz theory. Each chapter ends with a few well chosen suggestions for further study.

The reader is then propelled rapidly through, and sometimes over, the second half of the book, which covers a selection of behavioural correlates of physiological functions. There are sections of about 20 pages each on motivation, emotion, consciousness, frontal lobe localisation, learning,

personality and psychopathology; and then on to glimpses of social and aggressive behaviour, wanted and unwanted actions of drugs; and the book comes to a close with a brief discussion of the mind-body problem. Comments on the composition of this section must, to some extent, reflect personal biases; I missed any discussion of recent attempts to link neurotransmitter systems with reinforcement mechanisms, and the neuropharmacology of mental disorders receives scant attention. There are occasional jarring lapses into simplistic clichés—for example, "if mental illness could be reduced to a chemical problem . . ."; and, incidentally, imipramine is not a monoamine oxidase inhibitor.

The book is largely successful in its aim; it is interesting but not indigestible. As an hors d'oeuvres the basic ingredients are well selected, nice to look at, and they whet the appetite. One big snag is the price—an hors d'oeuvres at £9.25 probably means that most students would have to do without the main course.

R. Kumar

Dr Kumar is a Senior Lecturer in the Institute of Psychiatry, London, UK.

Behaviour genetics

The Genetics of Behavior. By Lee Ehrman and Peter A. Parsons. Pp. viii+390 (Sinauer Associates: Sunderland, Massachusetts; Freeman: Reading, June 1976.) £11.50.

BEHAVIOUR genetics is not easily organised into textbook form, as it's literature covers a very diverse range of topics in a patchy fashion. Ehrman and Parsons have chosen to group their material according to experimental approach and experimental animal. There are chapters on 'single genes and behaviour', 'many genes and behaviour', 'Drosophila', 'Rodents', 'other creatures', 'man—continuous traits', 'man—certain discontinuous traits', and so on. Their decision is reasonable but it presents them with problems, for such groupings are not the best for bringing out the main questions to which behaviour genetics should be applied. This book was written just too early to have taken account of the sociobiology upsurge. Here, for example, we have an infinity of attractive theories confidently proposing a genetic basis for a huge range of complex social behaviour. Yet we know next to nothing about the way the simplest behavioural potential is encoded in genetic terms. This main question quickly breaks down into a cluster of questions concerning genes and behavioural development, and gene environment interactions. Of course, these and other major questions do emerge from Ehrman and Parsons's book, but I think they should have been more strongly accented, to give some structure to their review of the very disparate literature, only a few of whose studies really lead somewhere.

This will, however, be a most useful textbook; it is certainly the best since Fuller and Thompson produced the first complete survey of behaviour genetics in 1960. Ehrman and Parsons write very well, their style is generally light and attractive. They begin with a chapter of essential genetics and I would judge that even students with no biological background could then go on with little trouble. The examples they cite are described thoroughly, with good illustrations and tables. Although I might quibble with the balance in places, they have certainly drawn together a scattered literature with great skill. Both authors are primarily geneticists and at times, I find the behavioural component lacking in depth. For example, their accounts of Dilger's work on hybrid parrots and Sharpe and Johnsgard's duck hybrids miss some of the points.

The chapters on human behaviour genetics are very good. The real test

here is the treatment of the genetics of intelligence issue and this is the best modern account I know, steering a very clear and reasonable course, missing none of the genetical or social issues.

Ehrman and Parsons end with a chapter on the evolutionary implications of behavioural changes, and then finally give their appraisal of future directions for behaviour genetics. I don't really share their conviction that it will emerge as a distinct discipline, but genetics will remain a vital technique in tackling some of the most fundamental behavioural problems. This textbook can be warmly recommended to teachers and students alike.

Aubrey Manning

Aubrey Manning is Professor of Natural History at the University of Edinburgh, UK

Ice on the land

Glaciers and Landscape A Geomorphological Approach. By David E. Sugden and Brian S. John. Pp. viii+376 (Edward Arnold. London, April 1976.) Boards £12; paper £5.95.

GLACIOLOGY and geomorphology are typical of many scientific subjects the early disciples of which, with a minimum of equipment, made bold observations from patient work almost always pursued in isolation. Since 1950 the pattern has changed to team work, sophisticated equipment, the sharing of investigation areas and special publications. Devotees from all industrialised nations meet regularly to learn of progress and methods, and to swap yarns of experience, always told with humour and understatement by those who, particularly in these two disciplines, raise their eyes to the hills from 'whence cometh their health'. Laboratory work has provided specific laws but the wide range of variables in natural processes in the field always raises new problems in the application of these laws to the observed landscape.

Glaciology is advanced primarily by physicists whereas geomorphology is lead by physical geographers. The authors are reputable glacial geomorphologists who appeal for investigations to link these two aspects more closely. The book systematically sets out a brief for the geomorphologist to recognise the scope of the ice problem and summarises what the glaciologist has done to assist.

There are five parts, each of three chapters. The first part, 'Glaciers and Glacier Dynamics', gives the basic properties of ice, the environmental factors influencing it, the morphology of

glaciers both *en masse* and in surface structure. Fundamental quantitative relations are limited to this first part.

'Glacier Distribution in Space and Time' provides a succinct summary of the ice on the Earth's surface and its fluctuations. The authors rightly criticise the overdramatisation by the media of the relation between glaciers and climate and conclude that reliable assessment of this relationship can only be made for high frequency events of low magnitude since precise data is only available for minor oscillations over the past few decades. The random element in oscillatory behaviour becomes more marked as the time scale increases.

The next two parts, 'Glacier Erosion' and 'Deposition', each give a chapter on process followed by ones on landforms and landscapes. Rock abrasion, meltwater transport and deposition of rock detritus, the characteristics of tills and the complex end-products of both processes are economically described. Meltwater phenomena extend well beyond the margins of present ice but the authors sensibly limit their account to the present glacierised phase.

The final part, 'Meltwater, a glacial subsystem', discusses a component in all glaciers that in recent years has received much attention from glaciologists and engineers. It is a very creditable account of an aspect that most authors have combined with erosion and deposition. As in the first part of the book, there is already new material to be incorporated, a common difficulty for authors in a subject developing so rapidly.

Each chapter ends with suggested 'Further Reading' and there is an index at the end of the book, preceded by 25 pages of references, since the authors have patiently sifted an extensive range of literary and photographic material, very well drafted and printed in the book. Almost every page has a diagram, a photograph, a table, a schematic model; and although the models are entirely qualitative and the authors admit that some will rapidly be superseded, most are new and will be welcomed by students being increasingly taught classifying systems.

Few books are better presented for the price and none more captivating to the reader interested in the fascinating phenomenon of ice on the land.

H. Lister is Reader in Physical Geography at the University of Newcastle upon Tyne, a member of the International Glaciological Society and of the British Geomorphological Research Group, and escapes to mountains and glaciers whenever possible. **H. Lister**

Dr Lister is a Lecturer in the Department of Geography at the University of Newcastle-upon-Tyne, UK.

obituary

Eric Higgs, who died in Cambridge on September 23 after a long illness, will be remembered especially for his contribution to economic prehistory over the past decade. He became an archaeologist at a time of life when most think only of retirement, after a first career as an economist and a second as a hill farmer. The impact that he made in his third career, as a research and teaching archaeologist at Cambridge University, is all the more remarkable for the fact that his health was poor—intermittently at first, but increasingly so with time.

He found prehistoric archaeology dominated by the belief that the key to understanding early man rested in the study of his artefacts and of the cultural groupings based on artefactual styles: the relationships between the prehistoric cultures were the cornerstone of the subject, largely divorced from the natural environment, and the ordinary economic life of prehistoric communities had been relegated by most prehistorians to a comparatively minor role in the history of early man. The study of prehistoric subsistence consisted of what he termed a 'horrid porridge' of specialist reports which, although embodying a considerable degree of technical competence in the analysis of biological data, usually did little to build an integrated picture of man's relationship with his environment. To Higgs, the emphasis on the importance of cultural data was fundamentally misleading, in that it obscured basic economic motives, such as the need for food, which were and are the vital core of human behaviour. By assigning subsistence to a central place in prehistoric archaeology, he did much to establish economic prehistory as an independent discipline based on its own concepts and supported by its own laboratory and field techniques.

These interests crystallised during his fieldwork in Greece (Epirus) in the

middle and late sixties. In 1967 he was appointed director of a British Academy Major Research Project to study the origins and early history of agriculture. From then until his death he presided over a hectic decade of original and fundamental research and fieldwork, in areas as diverse as Alaska and Israel, on periods as widely separated as the Middle Palaeolithic and the Mediaeval.

This research was important in two ways: a theoretical contribution to the study of prehistoric subsistence in general and early agriculture in particular, and methodological developments in fieldwork. His project undertook a long overdue reassessment of the basic concept of animal and plant domestication. He argued that it was unrealistic to expect that human subsistence in prehistory would divide neatly into hunting and farming; instead, there would have been a series of relationships between prehistoric men and their plant and animal resources. Prehistorians have yet to appreciate fully the implications of this reassessment, for they have yet to accept that when and where agriculture originated cannot be confined to a convenient postglacial Garden of Eden, or that its origins had better be re-defined on more sensitive and complex criteria.

Of the new techniques he introduced, some, such as froth flotation for retrieving botanical remains from habitation sites, or site catchment analysis for quantifying economic potential of the areas exploited from prehistoric settlements, were culled from other disciplines, and modified; others, such as sieving techniques for recovering faunal samples, were already in occasional use but have since become an integral feature of modern palaeoeconomic investigations. This fieldwork, embodied in two major publications—*Papers in Economic Pre-history* and

Palaeoeconomy—was conducted and published within five years and was usually undertaken on field budgets which would have confined many another expedition to the armchair. Higgs even made his students pay 5 shillings a day for the privilege of working 8-h on-off shifts (under floodlights if necessary) at the site. (Hammond Innes did his fieldwork for the novel *Lefkas Man* by watching Higgs in action in Greece.)

Inevitably, his research aroused much debate and criticism. Many of his colleagues felt uneasy about his conviction that prehistoric archaeology had hitherto been concerned with only trivial aspects of past human behaviour and few shared his sublime indifference to the vagaries of ceramic and lithic styles. Yet the simplicity of Higgs's viewpoint was its strength, for it provided a direct challenge to an ageing conceptual framework which had denied the biological basis of prehistoric human behaviour. As Higgs said, "did Man Make Himself and control his own destiny as Childe had taught, or did he, like Topsy, just grow?"

Those who knew him personally, could not fail to recognise him as a man of remarkable character. He was an utter individualist, with scant regard for convention in either his professional or his personal life. It was in keeping with the man that he merged both, and shared them with his students to a remarkable degree; in return he expected and generally received a degree of commitment that often surprised even those who gave it. Eric Higgs was a remarkable man, in particular a gifted and riveting teacher. Prehistoric studies in general, as well as the personal and professional lives of those who knew him, are much the poorer for his death.

Graeme Barker
Robin Dennell

Benjamin Franklin Howell, Professor Emeritus of Geology and Palaeontology, at Princeton University, died on May 28 at the age of 85.

Howell was born on September 30, 1890, in Troy Hills, New Jersey. At the age of 18 he entered Princeton University where he received his Bachelor's degree in 1913, a Master's degree in 1915, and a Doctor of Philosophy degree in 1920, all in the Department

of Geology. He remained at Princeton where he was appointed as Assistant Professor in 1920 and became Professor of Geology and Palaeontology in 1947. He also served as Curator of Palaeontology and Stratigraphy at Princeton from 1924 until his retirement in 1959.

In addition to his work at Princeton, Howell was engaged in adult education as Professor of Geology at the Wagner

Free Institute of Science in Philadelphia, Pennsylvania, from 1928 to 1947. He also served as part-time Curator of Palaeontology at the Academy of Natural Sciences in Philadelphia from 1937 to 1947 and as a Visiting Lecturer in Palaeontology at the University of Pennsylvania.

He was a recognised authority on the palaeontology of the Cambrian Period, the earliest geological period of abun-

dant marine invertebrates. He was one of the founders of the International Palaeontological Union, and served as its Secretary in 1936-1937 and as its Vice-President in 1938. He was also an Honorary Member of the Geological Society of London as well as of the Palaeontological Society of India. At various times he had served as a consultant for the United States Geological Survey, the United States National Museum, the Geological Survey of Canada, the Canadian National

Museum, and the geological surveys of Vermont and Montana.

In America Howell was an active member and officer in both palaeontological and geological societies: as a Fellow of the Palaeontological Society he served as its Secretary from 1931 until 1939 and as President in 1944, and was a member of several of its committees concerned with Cambrian fossils and stratigraphy. As a Fellow of the Geological Society of America he was elected Vice-President in 1945.

During the early 1950s he was Chairman of the Cambrian section of the National Research Council's Committee on Stratigraphy.

During his long career Howell was one of the more prolific writers in the geological profession. His bibliography includes more than 200 titles of geological and palaeontological contributions, dealing mainly with Cambrian marine invertebrates, especially trilobites.

Appointments

Dr Barrie Vernon-Roberts as Professor of Pathology at the University of Adelaide.

Mr A. R. Haly as chief of CSIRO Division of Textile Physics.

Dr D. G. Murchison to a Chair of Organic Petrology at the University of Newcastle upon Tyne.

Professor J. Heslop-Harrison as a Royal Society Research Professor, to be taken up at the University of Wales, Aberystwyth.

Professor G. W. Kenner as a Royal Society Professor at the University of Liverpool.

Professor J. L. Gowans of the University of Oxford will take over as the new secretary of the MRC in April.

Meetings

November 17, **Cumulonimbus Convection**, London (T. M. R. Whitwell, James Glaisher House, Grenville Place, Bracknell, Berkshire RG12 1BX, UK).

January 3-5, **Mathematical Aspects of Homogeneous and Heterogeneous Combustion**, Cranfield Institute of Technology, Bedford (The Secretary, The Institute of Mathematics and its Applications, Maitland House, Warrior Square, Southend-on-Sea, Essex, UK).

January 6-7, **Respiratory Gas Transport**, London (The Secretary, The Institute of Mathematics and its Applications, Maitland House, Warrior Square, Southend-on-Sea, Essex, UK).

January 17-22, **Gondwana**, Calcutta (Organising Committee, IV International Gondwana Symposium, The Geological Survey of India, 27, Jawaharlal Nehru Road, Calcutta-700016, India).

January 31-February 2, **Cadmium**, San Francisco (The Cadmium Association, 34 Berkeley Square, London W1X 6AJ, UK).

February 7-8 (Chicago) and February 14-15 (Brussels), **Laboratory Testing**

Person to Person

Applications for the Victor Heiser Awards for Leprosy Research are invited to apply to Ms Caroline R. Stanwood, Director, Heiser Fellowship Program for Research in Leprosy, 1230 York Avenue, New York, New York 10021. The awards are for. Postdoctoral Research Fellowships, \$10,000-14,000, applications from individuals or heads of departments, Visiting Research Awards (for specific research at distant institutions), Research Grants (possibly available for specific programmes).

Wanted: 3- or 4-bedroom furnished house in central London, preferably Ealing, from August 1, 1977 to July 30, 1978, in exchange for house in Halifax. Replies to Carl Abbott, M.D., Department of Medicine, Camp Hill Hospital, Halifax, Nova Scotia, Canada B3H 3G2.

M.I.T. professor offers a 12-room fully furnished Victorian home in Brookline, Mass., in exchange for a 7-room (minimum) home within reasonable commuting distance of central London for one year beginning July 1, 1977. Brookline is very near Harvard, M.I.T., and major hospitals; has excellent schools and public transportation. Please reply to Dr Harvey Lodish, M.I.T. 16-435, Cambridge, Mass., 02139.

for Cancer (Robert S. First, Inc., 405 Lexington Avenue, New York, New York 10017).

March 23-25, **Nuclear Physics**, Guildford (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1X 8QX, UK).

April 4-7, **Atomic and Molecular Physics**, Reading (K. Codling, Conference Secretary, J. J. Thomson Physical Laboratory, Whiteknights, Reading RG6 2AF, UK).

April 4-7, **Low Temperature Biological Microscopy**, Cambridge (Dr P. Echlin, The Botany School, University of Cambridge CB2 3EA, UK).

May 8-12, **Psychoneuroendocrinology**, Atlanta (Dr Richard P. Michael, Department of Psychiatry, Emory University School of Medicine, Atlanta, Georgia 30322).

July 13-15, **Processing, Structure, Properties and Performance of Polymers**, Nottingham (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1X 8QX, UK).

July 24-30, **Optimal Development and Management of Groundwater**, Birmingham (Dr J. W. Lloyd, Organising Secretary, IAH Symposium, Department of Geological Sciences, University of Birmingham, PO Box 363, Birmingham B15 2TT, UK).

August 22-24, **Scientific Instruments: Their Social and Economic Settings**, Greenwich (Organising Secretary, Department of Navigation and Astronomy, National Maritime Museum, Greenwich, London SE10 9NF, UK).

September 4-8, **Low Energy Ion Beams**, Salford (The Meetings Officer, The Institute of Physics, 47, Belgrave Square, London SW1X 8QX, UK).

September 19-24, **Behavioural Development**, Pavia, Italy (Secretary to the 4th Biennial Congress of the International Society for the Study of Behavioural Development, The Institute of Psychology of the Faculty of Letters and Philosophy of the University, Corso Strada Nuova, 65, 27100-Pavia, Italy).

nature*November 11, 1976*

The cost of Swiss francs

It is fashionable to see the late 1960s as a period when science on a worldwide basis went through a major transition, emerging with a much-changed relationship with society in general. That transition, even if major, was at least fairly gradual and allowed for steady adjustment in values amongst scientists. In later years we may well look at 1976 and decide that here was a second equally drastic transition, but one which occurred in the course of weeks rather than years and which affected only Britain. The continuing weakness of the pound—a result not of irresponsible financial journalism, nor even of sterling's role as a reserve currency, but of long-term industrial inadequacy to compete successfully in overseas or even domestic markets—is precipitating a serious crisis of confidence among many scientists about the will, let alone the ability, of Britain to continue as a pre-eminent scientific nation. Much of this alarm is exaggerated, there is no doubt, and there is a danger that we all think ourselves into a worse crisis than really exists.

The details barely need repeating now. Every cent that the pound drops on the foreign exchange markets adds nearly £200,000 to the money that has to be found by the Science Research Council (SRC) to pay international subscriptions, notably to CERN, the European Space Agency, and the Institut von Laue-Langevin. The CERN subscription, at over £20 million, is by far the greatest. The recent downward trend of the pound has thus meant severe economies for domestic programmes in no way related to high-energy physics, even those of other research councils. It has also meant that Britain has had to put out some very careful feelers to CERN and its member states for sympathetic understanding.

What are the options at Geneva? It would conceivably be possible to pull out of specific projects there by way of economy. There has been recent speculation about dropping out of the Intersecting Storage Rings programme, which provides collisions at the highest energy in the world. But there seems no evidence at all that Britain has either taken or intends to take any such step, which would be the most ham-fisted way of disrupting CERN's operations. The danger is that such speculation,

especially in an international framework, can easily turn into a self-fulfilling prophecy. It is much more likely that SRC, if it fails to convince the Treasury that support for an international treaty should be detached from a national policy on cash limits, will go to CERN to see if there is any way that the UK can reduce its overall contribution while maintaining its membership of all programmes. It goes without saying that to have to do this would hardly enhance our reputation as a partner in European ventures.

It is difficult as yet to predict how our partners in CERN would react to such an approach. No other country seems to be experiencing similar problems; Italy might seem the most vulnerable but pays directly from its Foreign Ministry, which has been in the habit of paying without question. One suspects, however, that there will be genuine support, provided that this is not to be an annual affair. The only difficulty is that the Germans, who might logically be bearers of a greater burden, already contribute 25% of CERN's budget, which is the limit that any country may carry. Thus any load shed by Britain could possibly prove an embarrassment for a smaller country to pick up.

But where in all this is the turning point for British science? Will this not seem a relatively minor ripple in hindsight? There are grounds for thinking otherwise, that the affair could polarise the scientific community to its great detriment. There has, of course, for some time been a substantial "anti-big science" feeling only just below the surface in many sectors of the community; the events of the past few weeks with their resultant stringencies across the board can hardly have helped dissipate this feeling. On the other hand the high-energy physicists now make no secret of dissatisfaction with the way SRC plans to shift emphasis in its domestic funding. In particular many are expressing a new-found concern at the council's growing emphasis on engineering research.

Whatever the merits of either of these points of view, they are symptomatic of dangerous splits and uncreative tensions which could very easily harm Britain's research potential and lead her down a depressing road to second-rate status. □

The loneliness of the original investigator

Ernest Borek of the University of Colorado Medical Center comments on the fate of original research under present funding arrangements

THE curse on science is that its masters demand results they can readily comprehend. Kings and princes once gave what we would call today research grants to their alchemists, expecting gold for their largesse. The alchemist Hennig Brandt serendipitously discovered that if he performed some hocus-pocus on dried urine, he obtained a magic stuff. It glowed in the dark! His patron, a German prince, was not impressed, so Brandt's grants continued to be miserly.

Of course, Brandt discovered phosphorous, and our knowledge of the universal need for this element in the form of phosphates by plants and the consequent incorporation of it into fertilizers has improved the yield of crops, producing wealth over the scores of years, which in value probably exceeds all the gold of the world.

Our situation today is not much different. We are the remittance men of Presidents and Royal Commissions. Science is in the political arena; we are at the mercy of the ringmasters. Charles G. Wilson, a Secretary of Defense whose department controlled enormous funds for research, pithily (if ungrammatically) aphorised the opinion of many upper level administrators on research: "Basic research is when you don't know what you're doing".

Five years ago the President of the United States decided, it being a pre-election year, to sign the "Conquest of Cancer Act of 1971", and did so with a flourish. He invited a horde of television men, some legislators, and a sprinkling of scientists to witness the great moment. I am ashamed to admit that curiosity impelled me to accept the invitation. In those pre-Watergate days, I was almost touched when the president told us about his dear aunt who died of cancer. In less than a year he impounded a hundred million dollars from cancer research provided by the bill he signed with so much emotion.

The British scientist is also not free from the paralysing shackles of authority. A few months ago, a young Englishman spent a year in my laboratory learning the skills to study the modifications of tRNA. He went home filled with plans and enthusiasm. He actually made an observation which could have been developed into something very interesting. But soon I received a sad letter from him. The

director of his research institute ordered him to drop studying modification of tRNA because the molecular biologist on some high MRC committee put a very low priority on such research. Chalmers were in vogue.

Now this is hearsay and may be just sour grapes, but I could count on the fingers of one hand the British colleagues contributing visibly to this field. For the benefit of those who are not molecular biologists, I should point out that the primary structure of tRNA is made by one enzyme, but more than fifty modifications of it are achieved by perhaps 150 different enzymes. We know the functions of some of these modifications, but for most of them, the gold is not yet visible. tRNA is the most versatile of the biomacromolecules. In addition to its pivotal participation in protein synthesis, it can regulate transcription of DNA, translation of messenger RNA and can even control enzyme activity. What new roles will be revealed by patient probings cannot be predicted.

The American scientist who strives for originality is bedevilled at two levels of the governance of science. The General Accounting Office (GAO), which is the administration's watchdog over the budget, has recently urged Congress to require annual reviews of all research grants awarded by the National Institutes of Health (NIH). One can just see the staff at GAO with their tidy accountant's minds fretting over the possibility that some scientist may goof off for three years. After all, the corporations from where they came give quarterly reports of their earnings to the stockholders.

Unfortunately, at NIH the administrators urge the appointment of young investigators to peer review groups. James Watson is the most vocal champion of youth on advisory bodies because, he says, creativity is exclusively in the provenance of youth. This may be true in mathematics, but has no factual basis in the biological sciences. A young scientist becomes visible in biological research at an early age not by original major contributions but by frenetic publishing in a field opened by the originality of others. Polish a little and publish a lot, that is the leitmotif of their research careers. "Peers" like that cannot possibly appreciate a new idea or a new approach. At the end of a two- or a three-year grant period,

they measure accomplishment by counting pages rather than by the increment in our knowledge. The grant application of one of our most distinguished cell biologists went unfunded recently; the reason, he was told, was that his proposed experiments were too bold.

The members of advisory panels at the National Science Foundation (NSF) tend to be more mature and accomplished. But Congress insists that grants be awarded for only two years. How can one pose a challenging question and dare explore it when within a year it is time to write the grant renewal? At a recent conference on nucleic acid modification I noted that pre-eminence in the technology of tRNA modification has passed from America to Germany and Japan, and the reason must be that no one in his right mind would dare tackle such a problem on a two-year NSF grant (*Nature*, September 9, 1976).

Some 25 years ago I became engrossed in Lwoff's discovery of lyso-genic induction. In four years, we filled notebooks with observations I did not think were worth publishing. Had I depended on our current system of research support, I would have been washed out. Yet it is a matter of record that from those four years of observation came the discovery of "relaxed control" of RNA synthesis, indirect induction of latent virus, post-synthetic modification of nucleic acids, and the first qualitative difference in a biochemical component of a tumor versus a normal cell.

To beat the system some investigators resort to artful dodging. You describe in your grant application your second level ideas, or experiments you have already done and thus gain time and resources to bootleg explorations of your pet ideas. Five years ago I foolishly described, among other things, a programme of study in tissue slices or *in vitro* of the functional effects of hormone-induced modifications of tRNA. The critique relayed to me was that I had no experience in that field and the funding was proportionately reduced. Needless to say, I went on to do what I wanted (see *J. Biol. Chem.*, **248**, 762; 1973, and *Nature*, **262**, 62; 1976). During these bootlegging operations, we observed serendipitously a novel attribute of the carcinogen ethionine (see *Nature*, **259**, 588; 1976).

Many years ago while an undergraduate, I supported myself and my family as a waiter in a restaurant where one of my duties was selling bootleg whiskey. Now I bootleg my research. *Plus ça change . . .*

Whither US science now?

Colin Norman surveys the post-election scene from Washington

WHEN it became clear shortly before dawn last Wednesday that Jimmy Carter had the electoral votes needed to put him into the White House, many Americans switched off their television sets and went to bed knowing who their next President would be, but not what he will do. Substantive policy matters were almost submerged in a flood of trivia during the long, tedious election campaign as the candidates' many rhetorical blunders, racist remarks of Cabinet members and non-political matters such as abortion claimed the spotlight. Although the campaign lasted many months and cost millions of dollars, it seems to have left most voters puzzled about where the candidates stand on the major issues.

Nevertheless, it is evident that Carter has offered the American people a very different political philosophy from the one which prevailed during the Nixon and Ford Administrations. As the Carter Administration takes shape over the next few months, it is likely to chart new courses in areas such as health policy, taxation, nuclear power, environmental protection and government reorganisation.

Little part for science

Needless to say, scientific issues played little part in the election campaign. Science policy is scarcely a partisan matter, and it hasn't figured prominently in election rhetoric since the Kennedy campaign, which took place in the post-Sputnik panic of the late 1950s. But when Carter takes office next January, he will be confronted with a number of important decisions which will have direct impact on science and technology.

First, however, it should be noted that Carter will enter the White House with at least lukewarm support from the scientific community. Though few scientific groups campaigned actively in support of Carter—in previous elections, groups of scientists campaigned for Kennedy, Johnson and McGovern—opinion polls taken among American academics found that Carter was favoured by a margin of two to one. A poll taken for the *Chronicle of Higher Education*, for example, found that 54% of the scientists surveyed favoured Carter, compared with 22% for Ford.

Carter's first chance to strengthen (or, indeed, to disrupt) his links with the scientific community will probably be in his appointment of people to fill

top science posts in his new Administration. Nearly 3,000 government posts are filled by Presidential appointment, and thus a change of President is usually accompanied by a wholesale change of top-level bureaucrats.

It is worth noting that Richard Nixon amply demonstrated the potential for souring relations with the scientific community in such matters. Early in his Presidency, Nixon vetoed the selection of Franklin Long as Director of the National Science Foundation because of Long's opposition to the anti-ballistic missile programme. Though the veto was made before Long's selection was announced, word filtered out and a shrill outcry was raised against political screening for that normally apolitical post. And Nixon incurred the wrath of many scientists four years later when he sacked the head of the National Institutes of Health, allegedly for disagreeing with White House policy on biomedical research.

Thus, Carter will probably tread carefully. His chief selection will be somebody to fill the post of science adviser and director of the newly-created White House Office of Science and Technology Policy (OSTP). Since OSTP was established by legislation, Carter is bound to retain it—indeed, he has already said that his science adviser will "provide a permanent and high-level relationship between the White House and the scientific community". The present incumbent, Guyford Stever, said when he was appointed last August that he would not stay long after the election, no matter who won. A widely-tipped candidate for the post is Lewis Branscomb, former director of the National Bureau of Standards and now head of research at IBM. Branscomb coordinated a science policy task force which advised Carter during the campaign.

The other chief science posts that Carter must fill are Director of the National Science Foundation and Director of the National Cancer Institute. The NSF post was vacated by Stever when he joined the White House staff and the NCI job was vacated in September by Frank Rauscher, who took a more lucrative job at the American Cancer Society. Carter is also expected to replace Russell Train as head of the Environmental Protection Agency. Though Train is generally considered to have

Carter: important decisions ahead

Ford: departure leaves vacancies

done a good job, the post is highly political and Carter made considerable mileage from attacking the Ford Administration's environmental record. On the other hand, Carter is expected to retain Donald Fredrickson as director of the National Institutes of Health. A skilled administrator, Fredrickson has earned a solid reputation and Carter is unlikely to risk provoking an outcry by replacing him for political reasons.

Carter will also inherit a top-level committee, chaired by Simon Ramo of TRW Inc, which was established by Congress to conduct a two-year investigation of federal science policy. The committee is scheduled to make its report and recommendations late in 1978, at which time Carter will have the option of retaining it as a senior White House advisory committee, or scrapping it.

Key policy decisions

As for the Carter Administration's likely policies for research and development, little is known with certainty, but many key policy decisions will have to be made in the

first few months after President Carter takes office. The following are some of the principal issues which Carter must decide.

● **Energy policy.** One area in which Carter has frequently attacked the Ford Administration's record is energy policy in general, and nuclear policy in particular. He has offered some specific plans for reorganising the federal energy bureaucracy, and for curbing nuclear proliferation.

Throughout the campaign, Carter made much of the fact that he was trained as a nuclear engineer, and therefore he claims to understand the problems associated with nuclear power. His attitude toward nuclear energy is decidedly cool, promising to minimise the United States' dependence on that source of power, but specifically stating that he does not support a nuclear moratorium. In particular, he has said that he will channel more energy research and development funds into alternative sources such as solar energy and geothermal heat. He has also promised to launch an aggressive energy conservation programme.

Carter has also offered a proposal to consolidate most of the departments and agencies now responsible for energy programmes into a single department. Included would be the Energy Research and Development Administration (ERDA)—which Carter has attacked as being overwhelmingly pro-nuclear—the Federal Energy Agency and the Energy Resources Council. The proposal is likely to meet stiff opposition in Congress, however, since many Congressional committees which now have jurisdiction over individual agencies would be wary of losing some of their authority. A prolonged battle should be anticipated.

On nuclear proliferation, Carter has repeatedly called for a worldwide moratorium on the sale of reprocessing and uranium enrichment plants, and for stringent controls on the export of other nuclear technologies. He has also proposed that an international conference be held to discuss alternative energy sources.

Perhaps the most important nuclear policy question confronting Carter, however, will be whether to permit spent nuclear fuel from commercial power plants to be reprocessed, and the plutonium extracted from it to be recycled as reactor fuel. Just five days before the election, Mr Ford announced that his Administration would defer a decision on reprocessing and recycling plutonium at least until the matter has been given more study. Many nuclear critics, including Carter, called the announcement "too little and too late", but Carter's own policies for

recycling have yet to be specifically stated.

Finally, Carter has promised to scale down the effort to develop a liquid metal fast breeder reactor (LMFBR), now the largest single federal energy programme. He has stated that he will reduce the effort to a relatively minor level and, perhaps, seek international participation in it. If Carter decides to

reject plutonium recycling and to scale down the LMFBR programme, those actions would constitute major defeats for the long-term plans of the nuclear industry.

● **Biomedical research.** Virtually nothing has been said during the campaign about the federal government's

Six-state nuclear battle: results

ALTHOUGH the nuclear industry in the United States is not too happy about the fact that last week's election will put into the White House a man who is decidedly cool toward nuclear power, it can at least take considerable comfort from balloting in six states. Voters in Arizona, Colorado, Montana, Ohio, Oregon and Washington soundly rejected propositions which would have placed crippling restrictions on nuclear plants in those states. A similar proposition was defeated in a seventh state, California, last June.

The propositions were rejected so decisively—by margins ranging from 58–42% in Oregon to 71–29% in Colorado—that the results constitute a stunning setback for the anti-nuclear movement in the United States. Spokesmen for the nuclear industry in fact wasted no time in claiming the outcome as a popular endorsement of nuclear energy. Carl Walske, president of the Atomic Industrial Forum, said last week, for example, that nuclear power "has been taken to the Village Square, as Einstein predicted, and has been approved by the American voter".

The defeats were particularly striking since opinion polls conducted only a month before the election indicated that the propositions stood a good chance of being approved in most of the states. In Colorado and Oregon, they were even leading by a margin of two to one. Anti-nuclear groups blame their defeat on the lavish funding poured into the campaigns during the closing stages by industry and labour groups anxious to swing voter sympathies against the propositions. Pro-nuclear forces are reckoned to have outspent their opponents by about 8 to 1, and it is noteworthy that in Montana industry groups put up more than \$80,000 to defeat an anti-nuclear proposition, even though Montana has no nuclear plants and no plans to build any.

The propositions would have forced new nuclear plants to meet three tough requirements before being put into operation. First, there

must be no limit to the damages which could be claimed by victims of a nuclear accident — at present Federal law limits the total liability per accident to \$560 million. Second, there must be an acceptable, proven technology for getting rid of nuclear wastes. And third, key power plant safety systems must be found to work satisfactorily. The last two conditions would have to be met to the satisfaction of at least two-thirds of the members of state legislatures. Those requirements are so tough that if they were passed in any state they would have virtually halted nuclear expansion in that state. Consequently, the industry fought them on the grounds that they would increase energy prices, discourage industrial expansion and increase unemployment.

The crushing defeat of the propositions in all seven states could have important national implications. For one thing it is likely to take the steam out of attempts in Congress to curb the growth of nuclear power. In the past few years, several bills aimed at halting nuclear expansion at least until a variety of conditions are met have been introduced. Though they have never enjoyed much Congressional support, if voters had demonstrated their enthusiasm for such measures by passing some of the propositions, anti-nuclear forces in Congress would have been given considerable impetus.

The outcome of the referenda is also likely to discourage similar attempts to limit nuclear power through direct ballot in the future. In fact, some nuclear spokesmen are already claiming that the crushing defeat of the propositions will lead to a sharp decline in anti-nuclear sentiment in the United States.

Although such claims will almost certainly prove to be exaggerated, the outcome of the referenda has clearly provided the nuclear industry with considerable ammunition to combat President-elect Carter's reservations about expanding the use of nuclear power in the United States.

\$2,000 million biomedical research programme, but again, Carter will be faced with some controversial decisions.

First, however, it should be noted that Carter's election may help reduce one of the chief problems which has plagued the federal biomedical research effort for the past few years. Major tussles between Congress and the Ford and Nixon Administrations over the size of the budget for the Department of Health Education and Welfare, of which NIH is a part, have frequently delayed the release of funds for NIH and thrown planning into confusion. The Carter Administration is likely to work more closely with Congress on such matters, and thus NIH's planning should be made easier.

Among the more touchy issues which Carter must sort out are whether to continue to support the training of biomedical researchers—Nixon and, to a lesser extent, Ford tried to phase out the NIH training programmes over noisy opposition from the scientific community. He will also have to adjudicate the growing controversy over whether the National Cancer Institute should continue to enjoy a privileged

position in NIH. In that regard, it may be recalled that Ford took a tentative step by suggesting that the cancer budget should be held constant this year while support for research on other diseases should be allowed to grow, but Congress increased the cancer budget anyway.

● **Arms control.** Though many of Carter's foreign policy statements have a distinctly hawkish ring about them, he has also criticised some arms control treaties as being inadequate. In particular, he has called for a complete cessation of nuclear testing, and he has labelled the proposed Threshold Test Ban Treaty as "totally inadequate". That treaty is now pending before the Senate for ratification, and it is likely that Carter will try to negotiate something more substantial instead of trying to get the measure through the Senate.

● **Congress.** Several key Senators and Congressmen who have been influential in science policy affairs have either retired or were defeated in the polls last week. The chief casualty was Senator Frank Moss, chairman of the Senate

Committee on Aeronautical and Space Sciences. But perhaps the most important changes are likely to come in the powerful Joint Committee on Atomic Energy, where the chairman, John Pastore, and Stuart Symington have both retired, and Senators Joseph Montoya and John Tunney were both defeated. On the House side, James Symington, the chairman of the subcommittee which oversees the work of the National Science Foundation, relinquished his House seat to seek election to the Senate. He has been an important defender of NSF during the past couple of years, but at least his loss will be partially balanced by the fact that John Conlan, NSF's chief critic, also relinquished his House seat to run unsuccessfully for the Senate.

Though many important science policy issues have been virtually ignored during the election campaign, Carter's handling of them in the next few months will be closely watched. Leaders of the scientific community are not usually reticent in giving policy advice to the government, and they can be expected to make themselves heard in the coming weeks. □

AUSTRIA

Nuclear consultation

Engelbert Broda writes from Vienna on Austria's nuclear energy information campaign.

UNPRECEDENTED action has been taken by the government of the Republic of Austria. In view of the wide divergence of opinions on the desirability or otherwise of nuclear energy and the emotions aroused, it has decided to consult the population on the matter directly. Although decisions will eventually have to be taken by Parliament, the government is making sure that the views of the people can serve as a basis. A nation-wide information and discussion campaign has been organised, financed by the office of the Prime Minister, Bruno Kreisky, in collaboration with the "Energy Section" of the Federal Ministry of Trade and Industry. The section is headed by Wilhelm Frank, a man with wide scientific interests who is not only a professional mechanical engineer but also a renowned theoretical mathematician and a philosopher.

Austria's energy position is relatively favourable. While for many years power consumption increased by about 7% per year, the rate of increase has, as elsewhere, gone down more recently. Hydroelectricity still accounts for more

than 70% of total electric power, and there are still unused reserves of hydropower, mainly along the Danube. (It is interesting, though, that a popular movement for the protection of the Wachau, the part of the Danube valley with the most beautiful scenery, has induced the government to shelve and reconsider plans for the exploitation of that stretch.)

The production of brown coal, mainly in Styria, is considerable and goes mostly to power plants near the pits. While normally some electric power is exported, in emergencies power can also be imported by high voltage transmission lines from west and east. About one-fifth of the oil and gas used in the country comes from wells in Austria. The necessary imports are widely spread geographically: sources include the Middle East and Russia. One nuclear plant, a 700 MW boiling water reactor on the Danube about 40 km north-west of Vienna, is in an advanced stage of construction.

That the first nuclear power station will be taken into exploitation is hardy in doubt. But although detailed projects exist for further stations, no decisions have been taken as yet. At a press conference held soon after the elections in Sweden that were so influenced by the nuclear issue, Austria's

Austria's Chancellor, Bruno Kreisky

Federal Chancellor cheerfully said that he was doubtful about the wisdom of more nuclear power, while the Minister of Trade, Herr Staribacher, expressed himself in favour of additional stations. In such circumstances the voice of ordinary people will clearly have a lot of weight.

The Federal Press Service has issued a little book containing basic information, as objective as possible, on nuclear power. There will be 10 public meetings in various towns where the members of the public may ask questions and offer comment for up to 90 seconds each. Each meeting deals with a different aspect of nuclear energy—

socio-economic problems, energy policy, safety, social repercussions, influence on climate and biomedical problems. The discussion on each subject can be held in one place only, but written contributions are also accepted.

Each meeting is prepared by a subgroup of five or six experts, including natural scientists, sociologists and economists. West Germans, Swiss and even an eminent Bulgarian are among the members. In preparatory meetings, each group tries to reach factual agreement as far as possible but does not hide internal divergences when it faces the meeting. Disagreements are bound to be pronounced as in every case both friends and foes of nuclear energy have been appointed to the groups. They do

not include, however, members of the nuclear establishment, notably employees of the companies that build or plan nuclear power stations.

The first public meeting was extremely lively. Following the meetings each group will submit an extensive report which will be further discussed publicly between adversaries and supporters of nuclear power. No party whip will be applied in Parliament, the Chancellor has said.

If in the end a major expansion of nuclear power production were rejected, Austria would have to take drastic steps to curb the further increase in power, and energy consumption generally. Alternative sources of energy, save undesirable imports, are in

the short term limited though the long term prospects for solar energy seem good. There is no doubt, however, that the scope for energy conservation in Austria is enormous: energy has been anomalously cheap, with oil prices low until 1974 and the sales price of electric power not keeping pace with inflation.

One perhaps inevitable, if regrettable, feature of the information campaign is the near-absence of a crucial issue: the subject of the plutonium economy and weapons proliferation. This problem is not so obvious to the citizens of a small and neutral country that spends little on the military; the success or otherwise of the bold venture they have embarked upon, however, will be watched closely. □

REPROCESSING

Permission to process

Gillian Boucher reports on recent developments in plans for the reprocessing of nuclear fuel in Britain.

THE decision last week by Cumbria County Council's Planning Committee to approve in principle the £600-700 million programme for the expansion of the nuclear fuel reprocessing plant at Windscale brings Britain perceptibly closer to becoming a world reprocessing centre. Unless Mr Shore, the Secretary of State for the Environment, exercises his option to re-examine the question within 21 days of receiving notification of the committee decision, outline planning approval is automatic. That will remove probably the greatest single impediment to the signing of the controversial nuclear reprocessing deal with Japan.

To gain planning permission will be an important victory for the nuclear industry which, since the negotiations with Japan were publicised at the end of last year, has been fighting a noisy battle with well-organised environmental groups. Fears centre on the prospect of Britain taking on long-term storage of other countries' fuels which she has reprocessed—becoming what the popular press has called the world's nuclear "dustbin"—and the dangers of sabotage if plutonium is shipped back to the country of origin.

After a five-month delay to the negotiations with Japan to allow time for public debate, Mr Anthony Wedgwood Benn, the Secretary of State for Energy, announced in March of this year that foreign deals would be acceptable if Britain did not have to store the fuels on a long-term basis but had the option of returning them

to the country of origin. But the Flowers Commission said in its report on nuclear power and the environment that it would be unwise to take up the option, that it was best to avoid transporting the wastes if possible and that long-term storage in geological formations would almost certainly be safer in the UK than in seismically active Japan.

The deal originally being discussed with the Japanese utilities was for British Nuclear Fuels Ltd (BNFL), the state-owned company which operates Windscale, to reprocess 3270 tonnes of spent Japanese oxide fuel during the 1980s. The deal was worth around £4000 million including a large

down-payment. But the delay for public debate gave the French reprocessing organisation, Cogema, a chance to declare its interest; both BNFL and Cogema, a subsidiary of the French Atomic Energy Commission, are partners in United Reprocessors, an Anglo-French-German market-sharing body. The final contract, now likely to be signed in the next few weeks, will probably share the Japanese work equally between Britain and France. British contracts with other countries are also being negotiated.

BNFL has had government approval of its plans to invest £245 million on extending and improving the existing Magnox fuel reprocessing plant and £40 million on development of the vitrification process; it still awaits the crucial approval of the £350 million

Windscale reprocessing plant

investment on Thorp, the oxide fuel plant, which will be vital if Britain is to become a big exporter of its reprocessing services. If business prospects continue to look good, permission will almost certainly be forthcoming.

Cumbria County Council has had a daunting task in assessing the application for planning permission—weighing on the one hand 2,000 jobs in an area of high unemployment and the prospect of much-needed foreign earnings, some of which have already been lost to France through delays, against unfamiliar dangers to a rural community on the other. The Windscale workers have been staunchly in favour of expansion and wanted the County Council to make its decision without further delay. But Friends of the Earth, Half-life, the Conservation Society and the Town and Country Planning Association among others, concerned principally with the oxide plant, wanted the matter referred to a public enquiry.

In the end the committee passed a resolution saying that it was "minded to approve" the application "subject to agreement of appropriate conditions" but passed the final responsibility over to Mr Shore as the application was a "departure from a fundamental provision of the county development plan". At the beginning of this week the Department of the Environment said it had still not received formal notification of the Committee's decision. The pressure groups will continue to call for a public inquiry in the little time remaining.

BNFL has been accused by the Lawyer's Ecology Group of providing

Why reprocess?

THE short answer is to make plutonium for fast breeder reactors. Though fast breeders will make us virtually independent of U_{235} sources, the supplies of plutonium and depleted uranium produced by the present generation of thermal reactors are essential for them. But much depleted uranium is treated before use in thermal reactors. Reprocessing also makes environmental sense. The 30% waste left after the removal of uranium and plutonium is more compact and easily stored than the untreated spent fuel.

A reprocessing works is essentially a straightforward chemical plant with elaborations necessitated by the radioactivity of the materials. The burnt fuel (uranium metal in the case of the Magnox reactors currently in use in Britain, uranium oxide for other reactors including AGRs and PWRs) is dissolved in nitric acid and the uranium and plutonium extracted with an organic solvent. The remaining highly active acid solution containing a variety of α and β emitters is at present stored in elaborate stainless steel tanks.

Incorporating the wastes in a solid would allow less hazardous storage, perhaps in deep boreholes either on land or under the sea. Solidification

also makes long-distance transport feasible and, if transport of wastes back to their country of origin is made compulsory, will be the *sine qua non* for Britain's role as a major international processor of nuclear fuels. A process of vitrification developed at Harwell in the late 1950s and known as Harvest has been taken up by British Nuclear Fuels who hope to be constructing a demonstration plant at Windscale by 1980. But the technological prospect is daunting, combining as it does intense radioactivity with the high temperatures needed for glass making.

Another large question mark hangs over the business of processing oxide fuel which, being more highly irradiated, poses greater problems than Magnox fuel. At present there is no commercial scale oxide fuel reprocessing plant in operation anywhere in the western world, though the La Hague plant opened earlier this year is approaching that level. At Windscale a "head-on" plant for pre-processing oxide fuel before it joined the Magnox fuel was in operation, but an accident in 1973 in which a number of workers were contaminated led to the closure of the plant. It is expected to reopen next year.

the County Council with "the sketchiest ever (application) ever offered for any major development" and of leaving it "until all the options were closed". But although the replies to the County Council's detailed questions were only

just ready in time for the public debate, Professor J. H. Fremlin, the County Council's independent scientific consultant, found he had all the information he needed to assess the dangers to the public at large. □

BRITAIN

A case of suitable treatment?

A number of members of the World Federation of Scientific Workers received inexplicable treatment from the Home Office when they tried to enter Britain for the federation's 11th General Assembly on September 17-23. Professor Eric Burhop of University College London, who is President of the federation, gave Nature his view of what happened

THE Federation's General Assembly, its highest policy-determining body, meets every three years. This year, on the occasion of its 30th anniversary and amidst some difficulty for many participants, the assembly was held in London, where the organisation was founded. Professor Burhop tells his story with the aim of preventing another recurrence in the future—the

assembly had once experienced even more serious difficulties some 15 years ago.

Before the latest meeting, says Burhop, a British MP associated with the affiliated organisation ASTMS explained to the then Home Secretary, Mr Roy Jenkins, the nature of the planned meeting and the countries from which the attending scientists would come. That was in February. Mr Jenkins' reply, according to Burhop, stated that he could see no reason why the assembly should not meet in London; but he added that people coming from countries from which visas were required should make their application in good time and certainly not less than two weeks before they wished to enter Britain, to give time for the necessary processing. "We informed our affiliated organisations

accordingly," says Burhop, "and expected there would be no more trouble. It was not until September 14, three days before the Assembly was due to commence, that we began to receive cables from delegates from distant parts that their visas had not been issued."

Burhop is quick to repudiate the frequent charge that the federation is a communist-controlled or Soviet-dominated organisation. That is not true, he says, and never has been. He summarises the aims of the federation as international scientific cooperation, the protection of the freedom and rights of scientific workers, the constructive application of science and international agreement on disarmament and the eventual abolition of nuclear weapons. He describes the attempts of the federation after the Second World War to hold meetings in London to discuss nuclear weapons as "sufficient to send sections of our

military and political establishment into a flat spin".

Official attitudes appear to have relaxed in recent years, but the federation's latest troubles, as told by Burhop, suggest that it is still viewed with deep suspicion. First to complain of difficulties was an Egyptian professor who had applied in Cairo on July 25 for his visa. Burhop says he received the last of several telegrams from the professor on September 16, saying that owing to the non-arrival of his visa he had cancelled his flight. The professor's visa was finally granted three hours before the commencement of the first meeting he was due to attend. A professor from Vietnam was the next in difficulties. He had applied for his visa five weeks previously at Hanoi, and it was granted on September 16—too late to catch the weekly direct flight from Hanoi to London.

Both professors had visited Britain previously without any difficulty, the Egyptian on many occasions. They were each able to reach London by circuitous routes, but some two days late. Four scientists who formed the delegation of the Organisation of Korean scientists in Japan were not so fortunate. They were members of the community of North Koreans who were stranded in Japan after the Second World War and not allowed to return to North Korea; unlike Japanese nationals, they needed visas to enter the UK, and re-entry permits to return to Japan. The Home Office gave the date of receipt of their visa application as September 2, which allowed the required two weeks for processing; the scientists claim that they applied even earlier. Their visas were granted on September 22, the day before the assembly ended.

But as Burhop points out, Home Office procedures were shown in the oddest light in the handling of the Soviet applications. After the French delegation, the Soviet delegation was the second largest at the Assembly. It consisted of twelve persons, including two Academicians, one a Nobel laureate and another a famous mechanical engineer, a James Watt medalist of the British Institution of Mechanical Engineers. Both members of the Supreme Soviet of the USSR (one is on its Presidium), they had visited Britain many times.

Burhop takes up the story: "There is a discrepancy in dates when the applications are said to have been made. Our Soviet colleagues claim that their Ministry of Foreign Affairs transmitted all the applications together to our Embassy in Moscow on September 3, exactly two weeks before the date of travel as specified by Mr Jenkins. The Home Office claims that they were received by our Embassy only on

September 8. Late on September 17 I was informed by the Home Office that three of the Soviet visas had been granted, the rest were under consideration, and no more would be granted until Monday. Of the three visas granted two were of secretaries to the delegation. The other was a social scientist and authority on disarmament. The Soviet delegation that sets great store on its distinguished Academicians was deeply offended. It read into the decision a studied insult, which I do not believe was intended, and I feared at one time it might develop into a diplomatic incident. The remaining Soviet visas, with one exception, were granted about midday on September 20, in time to permit the whole delegation with the exception of the scientist whose visa was refused to travel to London that evening. They were able to make an effective contribution to the rest of the Assembly."

Then there was the GDR delegation, which included the President of the GDR Academy of Sciences and a university rector. Their application was late, and was received only on September 10. The Polish delegation, however, applied at the same time and received visas almost on time. Visas for the whole of the GDR delegation were granted only on September 21. They arrived the following day and participated only in the tail-end of the assembly.

Burhop again takes up the story: "Of course I do not excuse those delegations who applied late. But some of those who applied very early were also very late in receiving their visas. I was informed by the person handling the visas at the Immigration Department that all the visa applications had arrived on his desk only on September 15 and only then could they begin the usual processing. This was despite the fact that as early as July our office in London had started supplying to the Home Office lists of all the delegates coming from abroad, details concerning whether they needed visas or not and, by early September, the name and country of each participant."

What went wrong? The change of Home Secretary on September 15 may have caused difficulties. The new Home Secretary, Mr Merlyn Rees, was absent from London on September 17 and September 20; it may be that the civil servants whose responsibility it was to take the decision were not willing to do so in the absence of the new minister. But Professor Burhop feels that no matter when the visas were applied for it made no difference: processing of them only started two days before the assembly was due to start and proceeded at a leisurely pace.

The most curious case of all is that of the Soviet delegate, Professor

Grigori Kotowski, whose visa was refused. One newspaper telephoned the Home Office and was told that Professor Kotowski was only an organiser, not a scientist at all. But according to Professor Burhop and others he is a social scientist of great eminence, deputy head of the Institute of the Peoples of Asia of the USSR Academy of Science and a leading authority on India. Kotowski has frequently visited the UK without any trouble, only last year attending on behalf of the USSR an executive meeting of the International Economic History Association.

Burhop speculates that the refusal of his visa was conceivably a matter of bureaucratic face-saving. Having boomed about the issue of visas the Home Office felt it had to refuse one to give the impression that there were very serious reasons for the delay. Alternatively—and less flattering to the Home Office—Burhop suggests a mix-up. "The name Grigori Kotowski is very well known in the Soviet Union. It is that of an almost legendary hero, a partisan leader, famed for his military exploits in Moldavia during the Civil War. There is an imposing statue to him in Kishinev. A tank regiment in the Red Army is named after him.

"Professor Grigori Kotowski is his son. A less military looking man or a man more academic or professorial in bearing than Professor Kotowski it would be impossible to imagine. But dare I suggest that the Home Office have got the records mixed up and that when they refused a visa to Professor Grigori Kotowski they mistook him for his father? Of course there is a small matter of fifty years between the careers of the two Kotowskis. Nevertheless in all this matter the Home Office has seemed so maladroit that nothing would surprise me."

The Home Office itself, when contacted by *Nature*, was hardly illuminating. The applications from North Korea, it admitted, did take a "little bit longer" than others. "We're sorry about it", a spokesman said, but "it took this time to clear. We take our responsibilities very seriously". Asked about the case of Kotowski, he explained that reasons were not given for the refusal of a visa; it depended a lot "on the relationships between one country and another". But he made a suggestion: why didn't *Nature* give the number of people who did receive their visas on time?

The response is printable. Of the 100 or so people attending, 41 required visas to enter Britain: 16 received their visas in time, 20 received them late and so missed at least 2 days of the assembly, 4 received visas too late even to attend, and one had his visa refused.

□

SCANDINAVIA

Controlling the pollution trade

Under a unique treaty which entered into force last month, private citizens living in the Nordic area will have the right to complain about and be compensated for damage to their environment caused by activities in their neighbouring countries. Mike Duckenfield reports

THAT the first agreement of its type should be reached between the Nordic nations is no surprise. Norway, in particular, suffers badly in the present European exchange of pollution and the Scandinavians as a whole are keen to secure international consensus on its control. In deciding to put their own house in order they are not only showing their seriousness, but aiming to preempt any criticisms about their own lack of action.

The agreement, prompted by the Nordic Council and covering all five of its members except Iceland, will be supplemented next January by Norwegian legislation requiring industry to use low-sulphur fuels. In October next year a start is due to be made to a seven-year Swedish plan to cut sulphur emissions to their level in the early 1950s.

The Swedish plan follows a recent government commission appointed by the Minister of Agriculture which carried out an extensive survey of air pollution problems caused by the burning of fossil fuels containing sulphur. It estimated that in 1973 about 60 million tons of sulphuric fallout, either dry or in precipitation, was generated in Europe, compared with only 25 million tons between 1910 and 1950. Of this, 38 million tons came from Eastern Europe and the remainder from the West. In addition, increased energy consumption in all countries was expected to result in the generation of 74 million tons by 1985, with 27 millions tons coming from the West.

In 1974, Sweden itself burned about 19 million tons of fuel oil, two-thirds of it heavy. As oil with a sulphur content of 2.5% by weight causes emissions of about 50 kg of sulphur for every ton of oil burned, it was calculated that about 800,000 tons of sulphur was emitted, a quarter of it from industrial processes using sulphuric compounds and the remainder from burning oil. If no action was taken this would rise to one million tons by 1985. As it is, the aim is to cut it to 300,000 tons.

To achieve this the Swedish plan involves banning the import and sale of light fuel with more than 0.5% sulphur

nationally from next October and, at the same time, prohibiting the use of heavy oil with more than 1% sulphur in the part of the country south of a line north-west of Stockholm. Two years later, the ban would extend to light oils with more than 0.3% sulphur and, in 1981, the extension nationally of the heavy oil ban. The plan also requires that the existing ban on burning oil with more than 2.5% sulphur be placed on other fossil fuels, most notably coal.

The programme would cost an estimated 500 million Swedish crowns (about £72 million) and includes government grants to finance the experimental liming of some of the 10,000 or so lakes that have been acidified by sulphuric fallout. At present it costs between Skr 400 and Skr 500 per hectare to lime the lakes and the job has to be repeated every five years.

For all this, Sweden expects to be able to do no more than maintain the *status quo* in the worst affected southern and western parts of the country. The reason is simply that most of the pollution is imported, mostly from the south and west across the North Sea and Baltic. In these areas it is estimated that less than 25 per cent of the fallout is Swedish in origin. In the remainder of the country the figure varies from between a quarter to a half of the total. Nationally it is just short of one-third. Because of this, the Swedes would now like to see total emissions in Western Europe brought down to between six and eight million tons within the next 10 years, a task that would cost about Skr 20,000 million a year.

In neighbouring Norway the situation is even worse with less than one-tenth of fallout being home-produced. Even in the area around Oslo, the country's most industrialised region, the figure only reaches 30-40%. The thin soil over much of the country does little to neutralise the acid rain and the build up of polluted winter snow leads to an annual mass slaughter of thousands of hatching and spawning fish when the spring thaw pours into the rivers and lakes. In the worst-hit south-west salmon and trout have disappeared from many rivers and a recent survey of 153 previously well-stocked lakes revealed the eradication of all types of fish from all but two of them.

So serious has the problem become that the Norwegian government is currently spending about £6.5 million in employing 60 full-time scientists on a seven-year programme to examine the effects of acid precipitation. And to draw international attention to the

need for control, the Norwegian Ministry for the Environment together with the precipitation project (SNSF project) this summer invited representatives from 20 nations including all but Luxembourg of the Common Market countries, the Soviet Union and three Eastern European nations to a conference at Gaustadblikk near Rjukan in Telemark in the south-west.

Research shows that not only are fish being killed, but acid rain is affecting soil productivity and could be causing decreased forest production due to the depletion of the earth's nutrients. Similarly, the Swedish commission report also points to the effects on urban areas due to the corrosion of metals and stone, especially limestone and marble. Costs of quicker replacement of materials and the need for corrosion protection were put at anywhere between Skr 100 million and Skr 1,000 million annually, not including the irreplaceable damage done to historic buildings and monuments.

While the conference could only agree to recommend nations to reconsider their approaches to emission control and to sponsor more research, international cooperation may be given a much needed boost with the publication of a report by the Organisation for Economic Co-operation and Development next year. OECD's recently completed research project into the long-range transport of air pollutants will show just how badly affected southern Scandinavia is. In one extreme case in January 1974, winds from all over Europe brought 4,000 tons of sulphate and dumped it over about 20,000 square km of southern Norway in just 12 days. Some areas had nearly a ton of sulphate per square kilometre. □

Pollution demo, Swedish-style

IN BRIEF

Appointment of GMAG chairman

The first chairman of the British Genetic Manipulation Advisory Group is to be Sir Gordon Wolstenholme, Director and Secretary to the Trustees of the Ciba Foundation and President of the Royal Society of Medicine. The establishment of a group to advise laboratories on appropriate precautions in genetic experiments was the main recommendation of the Williams working party which reported in August this year. The group will examine proposals from laboratories (though precisely which types of experiment will have to be submitted is yet to be decided), assess the hazards involved and advise on appropriate precautions. The names of other members of the group will be announced soon.

Customers for nuclear club?

The secret club of 13 nuclear exporters, which aims to restrict nuclear exports to countries which have not ratified the 1970 Non-Proliferation Treaty, is reported to be considering admitting customer nations to its circle. The group is expected to meet in London this week. Customer nations made their resentment of the group's clandestine activities clear at the International Atomic Energy Agency annual conference in September; it has been suggested previously that the group admit customer nations but some members, notably France, were against it. Iran is being suggested as a possible first customer-member, as its large nuclear programme involves exports from several countries including the United States, Germany, France and the United Kingdom.

French chemical controls

Production and import of chemicals in France will be much more strictly controlled in future if a draft law adopted by the Council of Ministers last week is passed in Parliament. Producers and importers will be required to make a study of the effects of new chemicals on man and the environment and make their results available to the authorities, who will have six months to decide whether the manufacture, sale or use of the chemical should be subject to regulations or even banned completely.

The measure will fill a gap in existing legislation, which regulates the use of specific products such as explosives, pesticides and food additives and protects certain defined groups. The new law will be the first of its kind in Europe.

BRAZIL is a country of extremes; wealth and poverty, grandeur and squalor, but above all, tremendous vitality and optimism. What other country could build such a fantastic new capital as Brasilia? Brazil is completely fascinating to a biologist, whether standing on a street corner in downtown Sao Paulo and watching the complete ethnic diversity of the hurrying crowds, or gazing from a plane at the unbroken green carpet of wild vegetation stretching for hundreds of miles below, without a sign of human impact. Or seeing the "mud house" nests of a charming bird, Joao de Barro, on the crossbars of most of the power line poles along the highway going south from Porto Alegre.

Brazil is where the high technology of the 1970s is brought to bear on one of the last great untouched areas of the earth. Can we hope that enlightenment will come in time to enable this country to escape the rapacity of human beings and their new machines? Sometimes, the results of change are obviously beneficial. Large numbers of Japanese immigrants have come to Brazil in recent years. The farmers among them were accustomed to producing large yields from their tiny farms in Japan. They found that land was plentiful in Brazil, and they evidently apply the intensive methods they used in Japan to much larger farms. (Brazil is the world's fourth largest market for pesticides.) The result is that the huge city of Sao Paulo now receives a plentiful supply of splendid fruits and vegetables, probably for the first time.

I saw these commodities exchange-

ing hands in the big wholesale markets at midnight. The produce was as carefully packed and graded as if it had been intended for gift shops. The nutritional status of many Brazilians must have been greatly improved by the industry of these new farmers. But in some regions, malnutrition is

Brazilian dilemma

THOMAS H. JUKES

common. When I visited the Ministry of Health in Brasilia, I was told that vitamin A deficiency is so prevalent in north-eastern Brazil that the changes produced by it obscure the "Pap test" in women. Also, the deficiency causes blindness in many children. For people who cannot or will not eat green leaves, synthetic vitamin A should be added to food. It costs about three cents per million units—about \$150 for one million adult Recommended Daily Allow-

ances or for two million for children under four.

The huge Volkswagen factory at the western edge of Sao Paulo has helped to produce an "instant middle class" in Brazil. On city streets, drivers blow their horns and flash their lights at each other, to challenge the right of way, except when, as often happens, traffic is completely clogged.

A great question for the future of the biosphere concerns the fate of Amazonia, which includes six states and portions of three more. The Companhia Industrial de Amazonia was formed in 1966 for producing non-ferrous metals; Sudam is the agency for development of Amazonia including plans for iron ore and bauxite, for hydroelectric power, timber-cutting and raising cattle.

Twenty per cent. of the world's fresh water supply flows through the Amazon basin network of rivers. Amazonia's area is nine times that of France. Its colossal jungles have a canopy of green vegetation above a thin layer of fragile soil and resting on hardpan. When the jungle is cut down the topsoil tends to disappear, leaving an infertile base. It seems that little is gained by destroying the jungle, and at stake is one of the world's great photosynthetic factories for maintaining atmospheric oxygen. The birth-rate of Brazil, where Roman Catholicism is the state religion and divorce is not permitted, results in a population growth of about 2.8% annually.

Will a desire to preserve Amazonia override the pressures for Brazil's western expansion?

correspondence

Biological fly killer

SIR,—K. M. S. Aziz (October 14, page 544) misquotes F. E. G. Cox (August 19, page 646) when referring to the use of insecticides for the eradication of tsetse flies (principally *Glossina morsitans*) from some 27,500 km² of riverine vegetation in Nigeria. This was achieved by ground spray techniques and not by aerial spraying.

This is a point of detail and Aziz could well reply that it does not affect his argument that aerial spraying (as practised against *Glossina*, elsewhere in Nigeria and in other African countries) is an unsatisfactory method of controlling insect species. He gives as an example the resurgence of mosquitoes after an aerial spray operation over parts of Bangladesh. However, mosquitoes in Bangladesh present different problems to tsetse flies in Nigeria and it can be misleading to compare the two situations.

I suspect that the mosquitoes of Bangladesh re-appeared because the aerial spraying operations had no permanent effect on their habitats. Precisely the same would almost certainly have happened in time in the case of the tsetse flies of Nigeria had the habitat remained unaltered. However, Nigeria is a land-hungry country and the success of the anti-tsetse operations allowed a breathing space in which land cleared of *Glossina* was taken over by man and his cattle, altering the vegetation to such an extent that it no longer presented a suitable habitat for *Glossina*.

The moral of the Nigerian success story is that tsetse control operations should not be initiated unless there is a demand for the land occupied by the flies. Obviously, in order to prevent such evils as overstocking and soil erosion, exploitation of cleared areas must be strictly governed by well thought out development programmes.

Insecticides for tsetse control do have, and will continue to have for the foreseeable future, an important part to play in the development of rural Africa. By all means let us undertake research, as advocated by Aziz, on more specific biological methods of control; but Africa cannot afford to postpone action against *Glossina* until satisfactory alternatives to insecticides have been developed.

Your faithfully,

A. M. JORDAN

Langford, Bristol, UK

Nobel prizes

SIR,—I have found what I believe to be a significant correlation between Nobel prizes and Olympic games. Previously, the United States did not have the dominant position in science that it has achieved today. The Nobel prizes of physics, chemistry and medicine were never awarded to US scientists in the same year; now the situation has changed. In 1968 all three prizes were for the first time awarded to American scientists. The second favourable conjunction came in 1972 (seven titles out of eight, in the three domains). Now in 1976 there is again an American monopoly. The three remarkable events are significantly correlated in time with the Olympic Games.

Some friends of mine suggest that the

truly significant correlation is to be made with the presidential elections in the United States. Such a hypothesis is easily ruled out on the basis of the authoritative works of Einstein and Garfield. It is known that the presidential elections occur after, not before, the designation of the Nobel laureates. Einstein's theory of relativity (*Ann. d. Phys.*, 17, 891; 1905) excludes any time-reversed determinism. Then, the objectivity and political independence of Stockholm's academicians is attested by the fact that the Nobel prize correlates very well with the value of the distinguished scientific work, as measured in the Science Citation Index (Garfield, *Nature*, 242, 485; 1973).

Yours faithfully,

JACQUES NINTO

Paris, France

Stamps of scientific interest

On October 9 Sweden issued a colourful set of five stamps commemorating nineteenth century Swedish pioneers in various spheres of technology. Each of the stamps bears a portrait of the pioneer in question together with an example of the practical application of his contribution to technology.

These range from work on the use of solar energy (John Ericsson), a machine gun and hay-mower (Helge Palmcrantz), the first desk telephone (Lars Magnus Ericsson), a milk separator (Gustav de Laval) to the first spherical, self-regulating ball bearing (Sven Wingquist). It was this latter innovation which was later produced by the Swedish Ball Bearing Company (SKF), in Gothenburg, which was founded in 1907. L. M. Ericsson's first desk telephone of 1877 was the start of the L. M. Ericsson Telephone Company, now a world-wide enterprise.

Also issued by Sweden on October 9 were two stamps devoted to industrial safety. The first law on this subject in Sweden was passed in 1889, it also being then that the first inspectors were appointed. The present body both investigates hazards on the factory floor and carries out research on occupational health. The design of these two stamps consists

of two hands against a background of two cog wheels. The fingers and the cogs join to symbolize the interplay between man and machine.

Joint Oceanographic Assembly

from C. M. Yonge

The 4th Joint Oceanographic Assembly was held in Edinburgh on September 13-24. Thirteen organisations participated under the auspices of a group of international bodies led by the Scientific Committee on Oceanic Research of the International Council of Scientific Unions.

WHAT immediately emerges from these meetings is the enormous recent extension of knowledge in effectively all aspects of marine science. This comes very forcibly to one who worked at the Plymouth Laboratory when W. R. G. Atkins and H. W. Harvey were elaborating the first colorimetric methods for the quantitative determination of phosphates and nitrates which led to elucidation of the annual cycle of events in surface waters, and who first visited the now mighty Scripps Institution when this consisted of a single laboratory, pier and a few scattered staff houses!

Geology which was then of minor concern has since assumed supreme importance. The first impact of plate tectonics is now past. With the accompanying study of sediments, now cored in supreme depths by the *Glomar Challenger*, aided by isotope detection and carbon dating, it provides evidence for the history of the oceans which was inconceivable a generation ago.

The oceans have long been divisible into great latitudinal zones with surface cyclonic or anticyclonic circulations and underlying compensating currents, the deepest waters creeping slowly in an equatorial direction. Upwelling off continents and between diverging current systems appeared as the major means of surface enrichment. W. H. Munk (Scripps Institution, San Diego) now reveals that the greater part of oceanic movement is highly variable, that an a.c. rather than a d.c. circulation prevails. A series of casual currents produces eddies in midwaters. In the Atlantic, some appear to originate by the cutting off of marginal areas of the Gulf Stream but in

general their origins are obscure. Of their great significance there seems no question, absorbing, as Munk calculates, more than 90% of oceanic energy. The superficial zone of high productivity is revealed by infrared photographs taken from satellites. All previous estimates of marine productivity may need considerable modification.

Wartime studies associated with submarine detection revealed the ubiquity and variety of submarine noises, readily detectable because sound pressure in water is a thousand times greater than in air. As L. M. Brekhovskikh (Academy of Sciences of the USSR) reminded us, while we, on the surface, cannot hear the fish below, anything we say may be carried to them. Internal probing of the sea by high frequency ultrasound can provide an acoustic image where no optical image is possible. Meanwhile a widening series of surface measurements—of temperature, currents, wave heights, chlorophyll and sediment concentrations and of much else—become possible from the orbiting platforms of satellites.

The complexity of the marine environment and so of the biological processes within it was evident in many contributions. The greatest of fisheries is that for the anchovetta in the rich and cold upwelling waters off Peru. Productivity is irregularly affected by incursions of warmer waters, the dreaded 'El Niño', from the north. But what had appeared as a direct effect on the fish—and so on their original exploiters, the guano-producing boobies, cormorants and pelicans—now appears as much more complex. The actual nature of 'El Niño' is in question as reported by G. L. Kesteven and L. J. V. Gonzales (Instituto del Mar, Lima). The effect may be less on the adult fish than on their reproduction and on development and survival of young stages possibly predated by medusae and pelagic crabs. Already it seems that the relatively very low spawning stock of anchovies in 1975 has produced more abundant progeny than the more

numerous stocks in the sixties. Until the precise nature of controlling processes becomes clear there can be no certainty about future stocks.

The long term variability of conditions in the Baltic, as indicated by the known vagaries in the herring fishery since the Middle Ages, now fits within a more recently traced pattern of ocean change in the North Atlantic. Warming of these waters with accompanying northward extension of major stocks of food fishes, including development of a cod fishery off the west coast of Greenland, has been followed by recent cooling and withdrawal.

A discussion of conditions in the intensively studied North Sea by A. Lee (Fisheries Laboratory, Lowestoft) provided some insight into what can happen when a body of water is bordered by areas of intense industrial activity. Here the water is exploited for fish, the bottom deposits are a source of aggregates for use in the building industry and the deeper deposits contain large quantities of oil and gas. On the credit side, although domestic and industrial effluents enter in vast quantities, extensive testing has failed to indicate any serious accumulation of pollutants in coastal animals. In the North Sea the major risk comes from escape of oil, directly from the borehead or by fracture of a pipe line. In the open oceans there is a possible future risk when pollutants slowly building up in the profound depths regain the surface.

Removal of wide areas of gravel could certainly have devastating effects on bottom-living animals and especially on the deposited eggs of herrings. The closure of shallow water areas such as the Wash and the Dutch and German Waddensee—both possible—would destroy the nursery grounds of plaice and other food fishes.

The widely publicised destruction of herring stocks, due largely to their over-exploitation for industrial purposes, has strangely been accompanied by great increase in the stocks of mid-water and bottom-living round fishes, such as haddock, which also spawn a

year sooner than formerly, making nonsense of earlier predictions of future stocks. The phosphate content in the southern North Sea has actually doubled in the past 15 years. Here we encounter what must surely be a positive result of human interference. Opinions vary between explaining this as the result of increasing discharge of largely domestic effluents from the surrounding countries or as an indirect consequence of the destruction of the herring fisheries by way of a now much better nourished and more numerous bottom fauna.

These are but few of the topics that claimed attention in a programme which ranged from mathematical treatment of data concerning water movements to stratigraphy, and from man's use of oceanic lagoons to the possibilities of ocean engineering and of extracting energy from salinity differences.

One cannot but be impressed by the obviously increasing integration of marine studies which was reflected in the attitude of the participating scientists. Any venture on or in the high seas calls for international plan-

ning and the cooperation of research vessels from different nations, the greatest such achievement to date being the International Indian Ocean Expedition. It follows that assemblies such as this one are essential if scattered workers are to meet and plan common activities.

Yet this assembly met with a sense of impending difficulties or worse. The Law of the Sea Conference falters on but with the eventual possibility that the present freedom to conduct oceanic research may become hopelessly entangled with far extended and jealously guarded international boundaries. As the mineral resources of the land diminish, those of the sea, notably of the manganese nodules—with significant additions of other metals—so abundant in oceanic depths, become increasingly attractive. Here is an extreme case of "haves" and "have-nots" with only a handful of the wealthiest nations able to afford the equipment needed for oceanic research and so obtain information that could be withheld from others. Such problems may well come to preoccupy future assemblies. □

Anything new about reverse transcriptase?

from Karin Mölling

YES, indeed, but the news is somewhat embarrassing! Since the discovery of viral reverse transcriptase in 1970 the problem has been to transcribe native RNA templates into long representative DNA copies. The DNA synthesised has always been small compared with the viral RNA template and, furthermore, a small portion of the genome is represented in a greatly disproportionate amount. Last year some laboratories seemed to have come up with a solution to this problem: the reverse transcriptase under the then routinely applied enzyme assay conditions was starved of triphosphates (Collett and Faras, *J. Virol.*, **16**, 1220; 1975; Rothenberg and Baltimore, *J. Virol.*, **17**, 168; 1976). All one had to do, apparently, was to raise the triphosphate concentration, which resulted in a higher yield of long complementary DNA—admittedly, still in a very low absolute yield. I was probably not the only one who was told, when this news was brought home from a tumour virus meeting, that experiments under the new conditions were prohibited because of the expense of the isotopes! There seemed to be a way round when it was later published that a carefully optimised detergent concentration for disruption of virus would also result in a better

yield of long complementary DNA (Junghans, Duesberg, and Knight, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 4895; 1975). For a year radiochemical companies must have earned a fortune from deoxyribonucleoside triphosphates, as complementary DNA was being synthesised in the presence of high triphosphate concentration in many laboratories with the aim of obtaining restriction endonuclease maps of the viral DNA and of making more representative DNA probes for hybridisation experiments.

Now it becomes embarrassing: recently it turned out, that the problems were not caused by too low a triphosphate concentration but too high a magnesium concentration (Rothenberg and Baltimore, *Cold Spring Harbor Tumor Virus Meeting*, 1976). Magnesium chelates the triphosphates so that they cannot be used by the reverse transcriptase—a problem which can certainly be overcome by increasing the triphosphate concentration. If the observation turns out to be true, lowering the magnesium concentration will obviously do equally well. It may be a consolation for all those researchers who are tempted to consider themselves stupid for not having found this answer themselves that it had to be a laboratory like Baltimore's to come up

with it. However, the prevention of precipitation of triphosphates is not the only effect of magnesium. That "Mg is RNase"—a slogan known in many laboratories—may also be involved. Degradation of the template certainly presents an important problem in its transcription. This idea is supported by another recent study from Spiegelman's laboratory, which shows that addition of pyrophosphate—which probably inhibits RNase—to the reaction mixture gives a high yield of DNA complementary to poliovirus RNA used as a template (Kacian and Myers, *Proc. natn. Acad. Sci. U.S.A.*, **73**, 2191; 1976). This result will prompt all those who use reverse transcriptase as a tool for synthesising complementary DNA for hybridisation studies to apply these simple conditions immediately. The product obtained however, is single-stranded DNA; why no double-stranded DNA is synthesised remains unclear. This poses problems for subsequent analysis with restriction endonucleases which predominantly recognise double-stranded DNA.

Why was this work performed with poliovirus RNA? Analogous experiments with genomes from RNA tumour viruses are already in progress. Do they present greater difficulties than those described for poliovirus RNA—which is about the same size as a subunit from an RNA tumour virus (10,000 nucleotides)? The genome of RNA tumour viruses is known to contain obstacles for an enzyme which tries to read its way through completely. It runs into stop signs probably caused by the secondary structure of the RNA. This has recently been reported by Haseltine and coworkers from Baltimore's group who classified the DNA into discrete size groups (Haseltine, Kleid, Panet, Rothenberg and Baltimore, *J. Molec. Biol.*, **105**, 107; 1976). The DNA chains of discrete lengths are all initiated with the tRNA primer at a unique site along the 35S genome and grow by linear extension. The predominant size of the DNA is about 100 nucleotides. Surprisingly, even the longest DNA pieces obtained, (about 3,000 nucleotides) do not contain poly(A) transcripts from the 3' end of the genome. If one tries to compare these biochemical data with the beautiful electron microscopic pictures of the viral RNA which have become available from Davidson's group (Bender and Davidson, *Cell*, **7**, 595; 1976), no correlation between the lengths of the DNA size classes and the structure of the RNA can be detected. The complicated secondary structure of the RNA genome remains at present a specific problem for synthesis of a DNA provirus *in vitro*.

Another problem involved in

reverse transcription of the RNA tumour virus genome is caused by the unexpected position of the RNA primer. Why is the tRNA primer located close to the 5' end of the genome if the polymerase is supposed to start there for reverse transcription of the whole genome (Taylor and Illmensee, *J. Virol.*, **16**, 553; 1975)? There remains only a short way to go for the enzyme (from 3' to 5') until it hits the end of the template. The unexplained location of the primer immediately raised the suspicion that this was the reason for the small size and the repetitive nature of the DNA synthesised *in vitro*. It has recently been shown clearly that in fact the region between the primer and the 5' end of the genome was preferentially copied (Cashion, Joho, Planitz, Billeter and Weissmann, *Nature* **262**, 186; 1976). When fingerprinting the RNA protected by the DNA product they were able to identify the region of the RNA by means of the "cap" which is specific for the 5' end. A series of models have popped up immediately which postulate mechanisms by which the reverse transcriptase could still manage to make a complete DNA copy of the genome. A sequence complementary to the initially synthesised DNA piece may be present at the 3' end of the RNA genome which would allow circularisation of the RNA or bridging between two RNA subunits and continuation of the reverse transcription towards a complete copy. The first evidence for such a model was presented by Haseltine during the European Tumor Virus Meeting in October in Switzerland. His earlier observation mentioned above, that the polymerase jumps to the 5' end of the genome without copying the poly(A) region, gives indirect support to his newest result. A highly conserved constant region on the RNA genome next to the poly(A) tract at the 3' end which had been found in Weissmann's and Duesberg's laboratories while mapping the genome, could be a candidate for the complementary sequence. The chance of matching sticky ends in a test tube would then determine the yield of long DNA transcripts and may be low. This could be another reason why complete reverse transcription of viral RNA *in vitro* is difficult to achieve.

However, one should be able to circumvent this difficulty by applying a simple trick. Controlled heating of the viral RNA will knock off the tRNA primer and a new primer (oligo(dT)) could be bound to the poly(A) stretch at the 3' end of the genome. Why does the reverse transcriptase not synthesise a complete DNA provirus now? Other factors are possibly required? Unwind-

ing proteins involved in DNA synthesis have been well-known in bacteria for a long time and have recently been described in mammalian systems (Herrick and Alberts, *J. biol. Chem.*, **251**, 2124; 1976). Such proteins may be required for extending the RNA template or the complementary DNA for double-stranded DNA synthesis. Recently, the stimulating effect of some DNA binding proteins from chicken cells on the avian viral reverse transcriptase has been reported (Hung and Lee, *Nature*, **259**, 499; 1976). A protein factor associated with plasma membrane preparations from chick embryo cells also stimulates the avian reverse transcriptase (Padhy *et al.*, *Nature*, **262**, 802; 1976). A virus structural protein may even be a candidate for a factor involved in reverse transcription. □

Fire on heathland

from Peter D. Moore

A SECONDARY effect of the hot, dry summer in Britain has been the incidence of large numbers of fires, particularly on heathland and moorland areas. Some areas affected are of high biological interest and value, and conservationists must be asking themselves what the long term effects of these fires will be upon our flora and fauna, and also whether anything could have been done to prevent them.

Especially serious are those fires which have affected our National Nature Reserves, many of which are managed by the Nature Conservancy Council (NCC). These areas have been selected for their diverse biota and are usually the best remaining examples of particular habitats in Britain. Therefore damage to these areas is a matter of great concern. One of the worst examples of such damage during the summer occurred on the Hartland Moor National Nature Reserve in Dorset. This 637 acre reserve near Wareham is largely occupied by dry, *Calluna* dominated heathland. Several rare and diminishing species are found on the reserve, such as the Dorset heath (*Erica ciliaris*) and two reptiles, the sand lizard (*Lacerta agilis*) and the smooth snake (*Coronella austriaca*). As a result of the fire the original population of about 800 sand lizards has been reduced to an estimated 30. The destruction of the habitat has meant that the remaining animals have little chance of survival in the wild, so they have been captured and are being kept in vivaria at the University of Southampton until it is possible to reintroduce them. Even fewer smooth snakes have survived.

This fire occurred despite rigorous precautions. A ploughed, perimeter firebreak isolated the reserve from surrounding areas and there are internal, mown firebreaks. Unfortunately, a public right of way crosses the reserve and the fire began inside the perimeter. The internal breaks proved inadequate as a result of the drought.

Heathland is a habitat which is basically maintained by fire, so its recovery will undoubtedly proceed as in the case of past fires. There are three features, however, which make this fire particularly unfortunate. First, the extent of the burn; about 450 acres (over two thirds of the reserve) have been destroyed. This may slow down the processes of reinvasion and means that the refuge areas are small. Second, the involvement of reptiles which already have fragmented distributions. The heathlands of Dorset are now reduced to about nine extensive tracts and reinvasion from one area to another by lizards and snakes is unlikely because of the barriers of unsuitable land separating the heaths. A third unfortunate feature is the intensity of the fire, which has a serious effect upon the peat areas, such as the valley mires and flushes on the reserve.

Peatlands are particularly susceptible to fires during droughts, and several important British peatland sites have been damaged this summer. Parts of Thursley Common in Surrey are an example, also the raised bog of Glasson Moss in Cumbria. In a raised bog the growth of peat-forming plants and the subsequent deposition of their litter can raise a dome of peat four or five metres above their surroundings. The impedance of drainage by the peat mass results in a raised water table within the dome. Glasson Moss is a good example of such a mire. Part of it is managed by the NCC as a National Nature Reserve and this part (about 140 acres out of a total 600) has been very badly damaged by fire during the summer. Its vulnerability is obvious, being surrounded by old, partially drained peatlands and agricultural land.

Glasson Moss was surveyed for the NCC by Grieg (unpublished report to NCC: 1975) and, although he found that the central areas of the dome were of high quality botanically, he considered that this quality had deteriorated in recent years. It is believed, for example, that peripheral drainage is lowering water tables in the central area and it is known that the surface was badly burned in 1969. The whole *Sphagnum pulchrum* / *Rhynchospora alba* / *Drosera anglica* assemblage, typical of the central dome, is now becoming very scarce on Glasson Moss. Glasson Moss is not alone. Borth Bog in the Dyfi Estuary National Nature

Reserve, West Wales, has been burned again this year and this has become almost an annual event. Many such fires are known to be started deliberately by local farmers who often believe it to be a sensible land use practice in such areas, though often for purely superstitious reasons. At Borth Bog two plants are nearing, or may have reached extinction. These are the bog moss (*Sphagnum imbricatum*) and the brown-beaked sedge (*Rhynchospora fusca*); the latter was once widespread on the reserve but has not been seen there for the past ten years.

At both Glasson Moss and Borth Bog, the fire prevention measures are inadequate. At Glasson, firebreaks around the central area are mown, but this does not prevent the movement of intense fires during dry periods. At both sites there is a case for considering the construction of wide, water-filled ditches around the reserve boundaries. This would be expensive, but may be the only means of saving these vulnerable habitats.

There is also a need for more research into the recovery of peat surfaces from burning and its influence on species composition. Evidently such bogs have suffered some degree of burning in the past and have recovered. It is instructive to inspect the diagrams of exposed peat profiles from Danish raised bogs recently published by Aaby (*Nature*, 263, 281; 1976) which have charred layers running along certain horizons dating from Neolithic and Bronze Age times. The raised bogs recovered from these traumatic episodes, but what will be the outcome of recurrent, sometimes annual fires?

The Nature Conservancy Council in Britain has the responsibility for acquisition, management and maintenance of Nature Reserves and also for the commissioning of relevant research. Its record on the survey and on the acquisition side is quite good, but its success in the maintenance of acquired Reserves is not outstanding. True, conditions have been unusual this summer, but some of the damaging episodes, such as the burning of raised bogs, are regular, predictable events and the NCC must accept some responsibility for failing to take adequate preventative action in good time. No blame for this neglect can be placed with the regional and field staff who have done everything possible within their present limited economic and physical resources. One cannot help feeling, however, that in the case of mature, self-sustaining ecosystems like the raised bogs the NCC considers its responsibilities to end with acquisition and neglects the assignment of funds to their protection. Let us hope that the sad events of this summer will lead to

the redeployment of money and manpower from the administrative to the field management and research aspects of nature conservation. We need fewer paper clips and more gum boots. □

The blind white fishes of Persia

from a Correspondent

A NEW species of blind loach captured in the Zagros Mountains, Iran, has recently been described by Greenwood (*J. Zool., Lond.*, 180, 129–137; 1976). In itself this is both interesting and remarkable, but it also represents the successful culmination of a quarter-century of interest in Iranian eyeless fishes by their collector, Mr Anthony Smith.

In 1950 Mr Smith led a party of students from Oxford University on an expedition to Kirman in Iran; one of their objectives was to study the fauna of the qanats, artificial underground aqueducts which convey water from the foothills of the mountains to the plains villages. In particular, they hoped to capture fishes which literary sources suggested were blind and depigmented and lived in the channels. On the expedition's return, Smith published a most entertaining account of their adventures (*Blind White Fish in Persia*, Allen and Unwin, London; 1953). Unfortunately, and despite this title, the expedition failed to catch any blind fish (although apparently fishes were found in the qanats they were not described or identified).

In the interval between planning the expedition and its accomplishment, however, Bruun and Kaiser (*Dan.*

scient. Invest. Iran, 4, 1–8; 1950) published a description of *Iranocypris typhlops*, found in 1937 in a subterranean water system outlet in the Zagros Mountains in southwestern Iran.

In 1976 Anthony Smith returned to the area, and visited the well-like outlet in which *Iranocypris* had been collected. Here he caught three colourless fishes, two of which he brought back to Britain. One of them proved to be *Iranocypris typhlops*, the other, surprisingly, was a loach new to science which Greenwood has just named most appropriately in honour of its collector, *Noemacheilus smithi*.

The loaches are freshwater fishes of wide distribution in Eurasia (although they are also found in north-east Africa); they belong to the order Cypriniformes which also includes the carp-like fishes. Although numerous species are known, particularly in the Asiatic region, this is apparently the first typical cave-dwelling noemacheiline loach to be recognised. Earlier authors had discussed loaches in Assam and an unspecified part of India which had been found in caves, but in neither case were the specimens completely depigmented, nor were the eyes greatly reduced (although there seems to be uncertainty as to whether the latter population showed eye reduction at all).

Noemacheilus smithi, however, is as typical a cavernicolous fish as any described. Its eyes are completely absent (as far as macroscopic examination could establish); the orbit on dissection appeared to be a shallow depression filled with minute fat globules. In life, its coloration is dead white suffused with pale pink, the viscera are visible through the abdominal wall, and the redness of the gills can be discerned through the gill

FIG. 1. *Noemacheilus smithi* sp. nov., holotype. (a) Lateral view (b) Dorsal view (c) Ventral view of head O -- position of orbit

cover. In other respects it is similar to other noemacheiline loaches, but the body is more slender than in most species, and there is a long, rather deep adipose ridge along the back behind the dorsal fin. The barbels around the mouth are, if anything, shorter and thicker than in other related loaches.

In a sense this discovery whets the appetite for more exploration in the area. The site in which both blind fishes were discovered is a well-like outlet, fully exposed to light, and in no way a cave. This poses the question, where are these fishes really living? Presumably the well is in contact with a subterranean water system in which both blind fishes live in some numbers. This, as yet, has not been discovered, but it could prove of great interest as this site where two fully-adapted cave fishes co-exist is only paralleled in the Mammoth Cave, Kentucky, a well explored system. Perhaps future exploration will yield further cavernicolous animals in Iran.

Iran's Department of the Environment, so helpful to Smith on his journey, has sent biologists to the area twice to collect further specimens. They found two more of the previously undescribed loach, which are currently being examined at Colorado State University, and plan a further expedition to the cave outlet this winter when water levels rise at the beginning of the rainy season. □

The theory and practice of star formation

from Ant. Whitworth

A Symposium on Star Formation was held by the International Astronomical Union at the University of Geneva on September 6-10.

STARS have formed in the past, and are continuing to form. Of this much we could assure the puzzled Huckleberry Finn who pondered "whether they [the stars] was made, or just happened": but of little more. Ultimately, self-gravity must drive the enormous contractions which convert diffuse gas into new stars. But the critical circumstances of this contraction—as the material destined for stardom overcomes the inhibitions posed by the internal thermal pressure, magnetic stresses, centrifugal acceleration, tidal disruption and turbulence—are extremely uncertain. The standard belief

is that most stars form in clusters, and the primary aims of star formation theory are then to predict, first, the distribution in mass, and in phase-space, of stars formed in a cluster, and second, the evolution in time of the external appearance of a star cluster during formation. To this end, four stages might usefully be distinguished: (1) the creation of a massive proto-cluster cloud, (2) the separation of individual protostars from such a proto-cluster cloud; (3) the contraction of a protostar to form a star, and (4) the interaction of a newly formed star with surrounding residual matter until the star becomes visible at a distance as a nonaccreting, unobscured, main-sequence star. (This fourth stage is included because it provides almost all the observable evidence of star formation).

At the symposium it was clear that, although the recent flood of observational data throughout the electromagnetic spectrum has tried many established star formation theories and spawned several new theories, much work lies ahead before star formation will be understood. For instance, the role of a spiral density wave and its associated galactic shock in initiating formation is very uncertain: whether it be to force a phase-change on the interstellar gas, thereby converting intercloud gas into clouds; or to assemble massive proto-cluster clouds by running together pre-existing small clouds; or simply to trigger by compression the gravitational collapse of pre-existing massive clouds. If we introduce the equally uncertain—and presumably coupled—role of magnetic flux, cosmic rays and their associated instabilities, we have already posed a long chain of unanswered questions and are still a long way from forming stars. B. Bok (Steward Observatory, University of Arizona) pointed out that there is extensive continuing star formation in the Magellanic Clouds; nowhere is the evidence more clearly laid out in the sky for the observer; yet there is no clear indication that star formation is very intimately involved with spiral structure, let alone an associated shock.

If such questions are put aside, and the existence of a gravitationally bound proto-cluster cloud is adopted as a starting point, we confront the problems of separating out individual protostars: by fragmentation or condensation, accretion or accumulation. Are protostars formed by an hierarchical fragmentation sequence which breaks the proto-cluster cloud up, in a cascade towards increasingly small, dense pieces, as originally envisaged by Hoyle? More probably, contemporary protostars condense directly out of a relatively low background density

($n \lesssim 10^4 \text{ cm}^{-3}$) due to gravothermal instability. Certainly no clear evidence for hierarchical fragmentation has been found in radio line (for example, CO) mapping of molecular clouds, in spite of the use of ample resolution—although any information would surely be a complicated convolution of density, temperature and optical depth structure. The only clear observations of fragmentation during star formation are (1) the high incidence of binary and multiple star systems, which implies that the inception of a typical protostar occurs in circumstances dominated by angular momentum, and (2) young clusters compounded by OB associations.

C. Lada (Center for Astrophysics, Harvard University) and B. Elmegreen (Princeton University Observatory) drew attention to a significant pattern observed in star formation regions. Ideally, this pattern is a regularly spaced alignment, parallel to the galactic plane, of first an elongated, quiescent molecular cloud; then an excited molecular cloud exhibiting signs of internal activity and star formation (infrared sources, masers and compact radio HII regions); next a compact OB association collectively exciting an extended optical HII region; following this an expanded OB association; then an even more expanded OB association. They submit that this sequence may arise as follows. An OB association formed in the front end of the cloud excavates an HII region, and sends an ionisation front back into the cloud. This ionisation front is preceded by a shock front, and after a time there is a shocked layer of neutral gas between these two fronts, which is sufficiently dense and cold for a new OB association to form by gravitational instability. And so the process repeats itself with a period of $\sim 2.5 \times 10^6 \text{ yr}$, producing a string of OB associations at intervals of $\sim 15 \text{ pc}$.

Given the considerable uncertainty which surrounds the inception of protostars, it is very difficult to predict the statistics of newly formed stars. C. Low and D. Lynden-Bell (Institute of Astronomy, Cambridge) have made a detailed evaluation of opacity-limited limit of $\sim 0.007 M_{\odot}$ for the local con-fragmentation and derive a lower mass temporary gas. J. Silk (University of California, Berkeley) has reproduced the Salpeter initial mass function (IMF) on the basis of opacity-limited fragmentation, and has also made several other quite definite predictions which occur with observational inferences: small stars form first at the centre of a proto-cluster cloud and heat up the outer layers, thereby increasing the Jeans' mass; consequently massive stars form later near the cloud surface.

Formation of the most massive stars,

however, is commonly assumed to involve an appreciable accretion phase. The upper mass limit is then attributed to an accretion cutoff, when the underlying star develops a sufficient ratio of luminosity to mass, that radiation pressure (acting through grains) halts the inflow. S. Strom (Kitt Peak National Observatory) suggested that accretion may instead be halted by a strong stellar wind. But the essential point is that Silk's IMF for fragments may not be completely relevant if the mass of the final star is much less than that of the fragment, the balance being contained in an unaccretible cocoon, as envisaged above (or perhaps in a disk which serves as a sink for the star's unwanted angular momentum). The final mass may then depend more strongly on the critical accretion parameters (density, opacity and velocity dispersion in the ambient gas).

Moreover, simple arguments show that if, at its inception, the protocluster cloud contains realistic measures of frozen-in magnetic flux and minutely conserved angular momentum, then subsequent contraction and fragmentation will amplify magnetic and centrifugal stresses until they assume dominant roles in the dynamic evolution. I. Mestel (Astronomy Centre, Sussex) pointed out that until—or unless—the charged particle density be-

comes very low, the gas is coupled to the magnetic field, and so clouds must tend to contract along the local field-lines; if the gas remains coupled to an attached, large-scale field for long enough, magnetic stresses may transport angular momentum from a cloud to its background, thereby postponing the development of centrifugal stresses until individual stars approach the main-sequence; by this stage the gas is recoupled to the field, and magnetic braking may again act to slow the rotation of the newborn star.

In conclusion, existing theory can say nothing about the overall efficacy of star formation. So many possible contributing processes can, at best, be evaluated in terms of their energetic feasibility, and seldom in terms of their competitiveness. Observations indicate that star formation in the solar vicinity presently converts ~5% of the interstellar medium into stars at each passage through the spiral pattern. Various attempts have been made to fit the mean rate of conversion of interstellar matter into stars with a law of the form $d\ln(\rho)/dt \propto \rho^n$, where ρ is the mean space density of interstellar matter, and n is to be determined by fitting observations. The results are conflicting and probably no such simple relationship exists where star formation is concerned. \square

ozone chemistry is not a theoretical myth but a reality in the stratosphere. It is not clear, however, how much of this observed chlorine comes out of the CFMs 11 and 12 and how much from natural sources like CH_2Cl , CCl_4 , and so on; what are the other competing reactions in which Cl atoms get involved to make them inactive for ozone reduction; and lastly, how many of them are removed from the stratosphere before they meet the ozone molecules. These are the uncertainties which led the NAS panel to put a factor of 10 on the uncertainty in their estimate of ~7% for the eventual reduction of ozone by CFMs. This implied that the eventual reduction of ozone could be anywhere between 2 and 20%. Several of these uncertainties were discussed at the conference. It appeared, for example, that the removal of Cl by the production of and eventual precipitation of the ClONO_2 molecule may not, after all, be such an efficient mechanism. Other uncertainties, however, remain. One hardly expected them to be answered only two days after the release of the NAS report. But one thing became very clear; with the amount of scientific activity in this field, this time next year the uncertainties will certainly be reduced by a significant amount.

The other scientific issue discussed at the conference was that of N_2O ; its sources and sinks near the ground and its eventual transport to the stratosphere. The problem, if it exists, could be greater than that of CFMs. It appears that N_2O , a product of biological denitrification in the soil, does not get easily "rained out" in the troposphere, diffuses on to the stratosphere, reacts with atomic oxygen, gets converted to NO and NO_2 , which then acts as a catalytic agent to destroy ozone in the upper atmosphere. Does this really happen or not, is of course an interesting scientific question for the students of ozone chemistry in the stratosphere. But the problem becomes greater when it is pointed out, as was done by Michael McElroy of Harvard last year, that the ever-increasing use of fertilisers may considerably accelerate the release of N_2O to the atmosphere with an eventual impact on ozone much greater than that predicted for supersonic aircraft, or the CFM.

Is this a real problem? We do not yet know. First, one needs much more precise information on the sources, sinks and life time of N_2O in the "natural atmosphere". What are the fluxes over the land and over the oceans? How much is the air-sea exchange? What is the life time of N_2O in the troposphere? What is the fixation time on the surface? Again, as in the case of CFMs, the theory seems

Stratospheric decision making

from S. I. Rasool

An International Conference on the Stratosphere and Related Problems was held at Logan, Utah on September 15-17, 1976.

It is refreshing to come out of a two and a half day international conference with a certain sense of accomplishment. This was partly due to the theme of the conference we not only discussed the physics and chemistry of the stratosphere, but one day was dedicated to questions related to the dynamics of decision making on the stratosphere. Nowadays when the stratospheric scientist has suddenly become an important individual, to both the media and the policy makers, interaction between the three was productive and satisfying, helped along by well-chosen speakers and panel discussions in which the major issues raised at each session, were if not solved, at least clarified.

In particular the conference took place two days after the much awaited release of the National Academy of

Sciences (NAS) report on the CFM problem. (*Nature*, 263, 268; 263, 723; 1976). After this conference and after the report where do we stand on the question of stratospheric impact of man-made products and what should be our attitude towards "regulation" of these products?

As for chlorofluoromethane (CFM) release, much progress has been made since the publication of the now famous paper by Rowland and Molina (*Nature*, 249, 810; 1974). We now know that most of the CFM 11 and CFM 12 ever released has accumulated in the atmosphere. We also know that a few per cent of them are reaching the stratosphere. There is also evidence that they are being dissociated, producing chlorine atoms which have a potential of catalytically reducing O_3 to O_2 . A major new set of measurements reported by J. Anderson (University of Michigan) confirmed, for the first time, the existence of Cl and ClO in the stratosphere. This was a crucial measurement that actually demonstrated that the chlorine-

to be in hand but the crucial measurements are just beginning to be made. As the Chairman of the Session, H. Schiff, put it. "We don't yet know whether the laughing gas problem is a 'laughing matter' or not".

The most exciting session of the conference was of course the one dealing with the dynamics of decision making and the topic under discussion was whether to "regulate" or "not to regulate" the use of CFMs 11 and 12 although the scientific evidence of the magnitude of their impact on ozone is still largely inconclusive. Policy makers from Washington, including the Chairman of President Ford's Council of Environmental Quality, discussed how decision making on issues of public policy proceeds in the face of scientific doubt.

About two million man-made chemicals now exist, and about 25 thousand are added each year. Since it is impossible to deal with them on a case-by-case basis, some general policies and philosophies are obviously needed. Those chemicals which have direct and immediate effects such as food poisoning or acute radiation exposure are of course easy to handle. For those chemicals whose effects are not immediately obvious and may occur several years or decades later, such as cancer-inducing products, or the CFMs, decisions on control have to be taken from a different perspective. In these cases public concern is not always an accurate indicator of acceptable risk and one has to keep in mind that often the values of the lives of the yet unborn are not assumed to be the same as those of our own. Sometimes it may also be unwise to postpone the decision until the effects can really be measured because a major impact may already have been made.

How then should we proceed? It was abundantly clear in the minds of the policy makers that although there remain valid doubts about the effects of CFM on the ozone layer, from the standpoint of public policy there remains no valid reason to postpone the start of regulatory procedures on the use of CFMs 11 and 12. They strongly suggested an immediate voluntary phase-out of non-essential uses of CFMs. This opinion was in direct conflict with that in the NAS report calling for a wait of up to 2 years depending on when the uncertainty can be reduced. The Academy panel was severely criticised for going beyond its charter and pronouncing judgement on a public issue. "There are no individuals better qualified to make scientific judgements than scientists. But scientists are no more qualified men than anyone else in making social value judgements," said Russell Peter-

son. "Moreover, this judgement carries with it added credibility simply because NAS made it and sets a strong public mood," added David Pittle, Commissioner of the US Consumer Product Safety Commission.

The debate between the scientists and the Washington bureaucrats was certainly educational for both. The scientists were reminded of their responsibility to present complex issues so that they could be understood by the public and that the uncertainty in their predictions is more evident than obscure. They were urged to place their own work (and bias) in perspective so that the media and public get a balanced view of the issues and answers.

For the scientists, so used to peer review and refereed journals, it was perhaps a little difficult to understand how one really assesses the importance of public opinion which is at once so volatile and so dependent on the media coverage of the news. We were assured by the Environmental Protection Agency that there were cost benefit analyses before any economic judgement was made and we were told that several months of public hearings take place before a judgement on the public opinion is made.

This conference was a satisfying affair. I think we all came home a little more reassured about each other and about each other's role in the eventual solution of the problem. □

Earth's core in Oregon?

from Peter J. Smith

LAST year Bird and Weathers (*Earth planet. Sci. Lett.*, **28**, 51; 1975) made the startling suggestion that josephinite, a rare rock consisting largely of nickel-iron alloy, may have originated in the Earth's core, or at least in the vicinity of the core-mantle interface. If this view were to be substantiated it would be of more than passing interest, for proven examples of core material in the crust are not exactly common. It would also carry with it certain implications about the Earth's ability to transport material over great vertical distances. Indeed, Bird and Weathers proposed specifically that josephinite may have been raised from the core-mantle interface in a mantle plume, carried into the lithospheric mantle by diatremes and emplaced into the upper crust by ophiolite obduction. But none of this exoticism was destined to go unchallenged; and Dick and Gillette (*Earth planet. Sci. Lett.*, **31**, 308; 1976) have now taken Bird and Weathers to task on a number of points which taken

together suggest a much less spectacular origin for josephinite.

The basis of the case put by Bird and Weathers was that the josephinite found as pebbles at Josephine Creek, Oregon, is distinct from the more common, albeit superficially similar, mineral awaruite. The chief differences claimed are that josephinite is much coarser-grained than awaruite and that, unlike awaruite, it contains two metal phases (nickel-iron alloy and α -Fe) and andradite garnet. Moreover, some josephinite samples also contain elemental silicon and a natural variety of the artificial substance $\text{CaO} \cdot 2\text{FeO}$, neither of which has previously been found in terrestrial rocks. Such differences were held to support the view that josephinite and awaruite have a different origin.

But even some of the facts are in dispute. Apropos of the reported discovery by Bird and Weathers of two metal phases, for example, Dick and Gillette claim that the metal in josephinite is all nickel-iron alloy, albeit with a "large bimodal compositional variation" between samples. There are indeed two metal phases, but one is awaruite and the other is taenite (rather than α -Fe), both of which are nickel-iron alloys. Dick and Gillette do admit that the association of the two metal phases with andradite in the samples analysed by Bird and Weathers is uncommon, although they point out that many of the pebbles contain only awaruite. They also quote a forthcoming report from Botto and Morrison which claims that there is in fact a complete gradation between awaruite and awaruite-taenite-andradite.

Next, Dick and Gillette throw doubt on the presence of elemental silicon in some samples which can be interpreted in other ways. In any case, they question the view of Bird and Weathers that the presence of silicon would preclude origin in the lithosphere, citing the production of impurity silicon in the smelting of iron as evidence of the element's ability to form stably at low pressures. The suggestion that andradite garnet/nickel-iron is not a stable assemblage (implying that the two components could not have formed together) is also disputed, largely on the grounds that Gustavson's (*J. Petrol.*, **15**, 455; 1974) experiments on the stability of andradite have been interpreted by some of his successors too uncritically and incompletely. And finally, Dick and Gillette suggest that the presence of diamonds in Josephine Creek, even if correctly reported (it is in fact in dispute), does not necessarily support the case that Bird and Weathers were making, if only because diamonds are representative of upper, rather than lower, mantle pressures.

Also relevant to that case are the dif-

ferences, or supposed differences, between the nature of the pebbles (which are placer deposits) and that of similar *in situ* material within the mass of the nearby Josephine Peridotite. The Josephine Peridotite, partly unaltered harzburgite and partly serpentinite, is apparently a segment of ophiolite emplaced by obduction. All parties agree that it contains awaruite in parts and that awaruite is formed by the serpentinisation of ultramafic rocks. They likewise agree that the Josephine Peridotite is the source of the pebbles.

But the consensus then breaks down. Dick and Gillette claim that both the *in situ* material and the pebbles are awaruite and (bearing in mind the nearness of the pebbles to a zone of intense shearing, serpentinisation and igneous intrusion within the Josephine Peridotite) that both are the products of low-temperature hydrothermal metamorphism and serpentinisation of the peridotite. Such differences as there are between the two (for example, it is acknowledged that the pebbles have unusually large grain size) represent varying conditions imposed by igneous

intrusion during serpentinisation.

Bird and Weathers, on the other hand, claim that the differences between the pebbles and *in situ* material are serious enough to imply a different origin (and to require separate names) for the two. Having acknowledged that the source of the pebbles is the Josephine Peridotite, having agreed that the *in situ* awaruite is the result of serpentinisation and having proposed a core origin for the pebbles, this would appear to put Bird and Weathers in the position of saying that the Josephine Peridotite once contained (and perhaps still contains) two distinct but closely related nickel-iron alloys whose zones of origin were separated by more than 2,000 km vertical distance.

Obviously it is possible. For example, a mantle plume could have been feeding the accreting plate margin from which the Josephine Peridotite is derived. But is it credible? If so, the exciting possibility of core material at the Earth's surface remains. If not, the balance of the argument must be in favour of Dick and Gillette who in any case have Occam's Razor on their side.

details of a number of sophisticated applications in nuclear physics. Following on from this, M. Lopenen (Otaniemi) introduced a lively debate on the problems and pitfalls of secondary thermometry.

One of the most fascinating, and perhaps also the most important, topics of the conference was reserved for the final day when K. W. Taconis (University of Leiden) and F. A. Staas (Philips, Eindhoven) talked about the new cycle in which instead of extracting ^3He from the dilute phase in the mixing chamber using a still, ^3He is pumped in through a superleak. This technique offers the great advantage that the dilute and concentrated phases counterflow in the same tube, rather than in separated tubes, so that no heat exchangers are needed. The simple Leiden machine, which reached 8 mK very soon after having been commissioned, was discussed in detail. Hybrid machines in which a "Leiden" mixing chamber is piggy-backed on a conventional refrigerator, and both ^3He and ^4He are separately circulated, as developed at Philips and Grenoble, were also considered. The meeting ended with an all-too-short session presided over by E. J. Varoquaux (Orsay) on the actual practical problems associated with operating refrigerators.

Notwithstanding the astonishing progress of the past 10 years, the dilution refrigerator is clearly still capable of significant improvement. If, as one suspects, commercial machines capable of reaching 5-6 mK soon appear on the market, it will be very largely a result of the beautiful research and development work currently in progress on this side of the Atlantic. □

Millikelvin technology

from P. V. E. McClintock

A Europhysics Study Conference on Dilution Refrigeration and its Applications was held at Lancaster University, UK, on September 25-27 1976. The meeting was organised by D. Thoulouze (Grenoble) and G. R. Pickett (Lancaster).

It is now more than a decade since the first dilution refrigerators were built. During this period the machines have become the standard means of reaching temperatures between 10 and 300 mK in a continuously operating mode and, moreover, the technique has spread far beyond the area of purely low temperature physics and is being widely used in a number of other fields.

Dilution refrigerators operate on a mixture of liquid ^3He and ^4He making use of the property that, at low temperatures, the liquid separates into two phases, usually known as the concentrated phase and the dilute phase. The concentrated phase consisting of almost pure ^3He floats on top of the dilute phase, which is composed of a gas-like assembly of ^3He atoms moving freely in a "background" of superfluid ^4He . Thus the movement of ^3He atoms from the concentrated to the dilute phase is very much like the evaporation of an ordinary liquid, and is

accompanied by a similar cooling effect.

The conference started with an introductory session led by H. E. Hall on what has become accepted as the conventional cycle: the "General Motors, rear-wheel-drive refrigerator", as he called it. In this cycle, ^3He is drawn out of the dilute phase by a heated still and the cooling effect arises from a balancing flow from the concentrated phase. The process is sufficiently well understood that machines capable of reaching 10-12 mK are available on the commercial market. The two sessions which followed led by G. Frossati (Grenoble) and A. Th. A. M. de Waele (Eindhoven), discussing the optimisation of this technique, provided what in many ways formed the high spot of the conference. It was particularly impressive to hear that the machines developed in Grenoble are able to reach 4 mK (not very far above the liquid ^3He superfluid transition) as a matter of routine and, furthermore, that their performance is in reasonable agreement with calculation.

On the second day some of the recent practical applications of dilution refrigerations were described in sessions led by R. E. Packard (University of California, Berkeley) and T. O. Niinikoski (CERN), and included

A hundred years ago

RUSSIAN newspapers announce the death of M. Chekanoffsky, who, exiled in Siberia, has spent more than ten years in the geological exploration of the country, and recently returned from his travels on the Olenek and the shores of the Polar Sea, to St. Petersburg, where he was engaged at the Academy in the description of his immense collections. He was found on October 10 dead in his room, and it is supposed that he poisoned himself. From *Nature*, 15, November 9, 50; 1876.

WHATEVER happens now, we cannot blame the Marxists for demystifying science. It's true that they were first in the field in England, shocking the bourgeois at the British Association at Durham in 1970 with their slogan: "Science is not neutral". But the point was soon reiterated to greater effect, not merely by Lord Rothschild's gauntlet, but even more by Sir Frederick Dainton's intended smooth covering. It was he who mentioned a "dangerous and corrupting 'ivory towerism'", to be countered by a continual awareness of "national needs and objectives" by those planning basic and strategic science. And since then we have all learned that the language of science is priorities, with a grammar of shrinking budgets.

Of course, the points are made with quite different motives from the two sides our established leaders want more 'civic responsiveness' from science, while the counter-slogan is 'social responsibility'. And the analyses of the situation of science diverge quite radically. Those who would manage science act on behalf of a social order assumed to be basically good, and capable of further improvement by the proper application of science. The Left critics exhibit science as a microcosm of an unjust society, and expose its hypocritical pretensions to superiority.

Indeed, the general impression that may be conveyed by the new double-decker edited by the Roses, *Ideology of/in the Natural Sciences*, is that of a many-sided assault on cherished illusions. For them and their collaborators science is neither innocent, ennobling, or even nice. The effect on a thoughtful scientist could well be similar to that on a benevolent, complacent male who picks up the *Spare Rib* that his women-folk avidly read, and discovers what he looks like from below. Although he may consider himself eminently fair in playing the game of social life, he is there told that the rules are rigged, for him and against the others. And if he is smitten with concern and guilt, he also learns that there is no easy cure for maleness as a social disease.

Similarly, those who enjoy the benefits of participation in the upper reaches of the institution of science are typically white and middle-class as well as male; thus they belong to a group whose security, until now enormous, is now decreasing markedly. Moreover (and this is an important thrust of the book), the character of the class of scientists is closely bound up with that of the science that they produce or apply. In its objects, methods and functions, our science is a creature of its matrix in a particular sort of class society. Stripping away the ever thinner veneer of 'pure science', these critics find that science is supported for its

Book review supplement

contribution to two ends: production, industrial and military, through physical inventions and discoveries; and social control, through its results, methods and above all ideology.

In this last point the authors initiate a major advance in Marxist thought.

Assault on cherished illusions

J. R. Ravetz

Ideology of/in the Natural Sciences (Two volumes.) Edited by Hilary Rose and Steven Rose. (Macmillan London, November 1976.) *The Political Economy of Science* Pp. 320. *The Radicalisation of Science*. Pp. 260. Each volume hardcover £10; paperback £3.95.

Until now, the Marxist tradition (along with positivism and rationalism) has assumed natural science (as best exemplified in physics) to be above the contradictions of society and independent of false ideology; from that firm basis, intending revolutionaries could proceed with certainty to transform the social world. The authors here are determined to exhibit the socially conditioned ideology 'of/in' natural science, without collapsing into relativism or irrationalism. This is a task of some delicacy, here only begun.

But a beginning there must be, and the authors have provided it, mainly (and properly) by accounts of areas they know from their own experience. These books have advantages and drawbacks of a largely amateur collection; there is repetition between essays

(as well as divergence of approach and doctrine), some looseness of organisation within them, and occasional bursts of rhetoric not intended for most of the readers of this present review. But generally, they are refreshingly free of jargon and bombast. And there are many insights to be gleaned in them, I shall try to convey some of these.

To accomplish this thoroughgoing critique, there must be a very broad definition of 'science', really encompassing all of theoretically trained problem-solving expertise. The most visible part, academic 'pure' natural science, is in this analysis reduced to a small, self-deluded sector. In one of their more breathtaking asides, the Roses remark: "By the end of the war, the autonomy of science had become a myth helping to ensure that those students with first-class degrees remained in the universities and those with seconds went into industry" (*Radicalisation*, p7.) Cruel, to be sure, but is it a complete caricature? And since there is no consensus on the boundaries of 'science', one must judge any proposed definition by the effectiveness of its use.

The Roses and their co-workers are not just demystifying and muck-raking. They are proclaimed Socialists, taking their inspiration from Marxism (although in what they call its "problematic inheritance"). Their essays are then both a criticism of capitalist natural science, and a demonstration of Marxist social analysis, as enriched by themselves. Their Marxism is the opposite of dogmatic; indeed it is easier to say precisely what it is *not* in terms

* Illustration of the "Book Wheel" taken from *The Various and Ingenious Machines of Agostino Ramelli*. Translated with an introduction by Martha Teach Gnudi and Eugene S. Ferguson. Pp. 604. (Scolar: London; John Hopkins University: New York, July 1976.) £50.

of the worries it relegates (environmental problems, and community and personal development), than what it is, by the articles of belief it maintains. Even the placing of the authors with respect to movements and powers in the contemporary world is rather vague, the book is dedicated to the "Heroic Peoples of Indochina", and there are occasional exhortations to workers; but otherwise it is all somewhat abstract. Even their citations to professedly Marxist literature on their subjects are very sparse. This independent policy has its benefits, of course; the authors are then entirely free to criticise capitalist culture on the basis of its own best values of liberty, decency and honesty—rather like Marx himself. Also, it enables them to move implicitly in some very interesting directions, of which more later.

What, then, can scientists see of themselves through this radicals' mirror? The Roses' leading essay "The Incorporation of Science" gives a synoptic view of the field (as their introduction gives admirable summaries of all the papers). The new conception of science, first described simply as 'big' but now as 'incorporated' or 'industrialised' subverts all the ideals of nineteenth century 'pure' science, and also many of those of the 'improving' tradition from Bacon to Bernal. But most academic studies of science (history, philosophy, sociology) are as yet only dimly aware of this transformation "from scientific community to scientific factory". Perhaps this is because they relate, not to the mass of *scientific workers* who are found to be indifferent to the hallowed 'norms' of science, but to the visible elite. This group can be identified; some 0.01% of the American scientific work-force of 2 million are the real decision-makers. And it is in their interest to maintain the myths of autonomy and 'public knowledge' as the ruling ideals of science. With this demystification accomplished, the book is launched on *The Political Economy of Science*.

An analysis of modern science-based industry that is broadly in line with classical Marxism is provided by Mike Cooley. He describes the proletarianisation of white-collar and technical labour, along with the continued dehumanisation of production-line work through Taylorism. His own experience in AUEW-TASS provides thought-provoking examples: computer-aided design, distorting the balance between the quantitative and the qualitative and leading to a stifling machine-enforced bureaucracy in the design process; attempts to restrict factory recruitment to men under 30 (they 'burn them up' in 10 years); the series of three strikes necessary to get heating and ventila-

tion for workers comparable to that provided for computers. This ultra-high technology industry aggravates many of the contradictions of capitalism analysed by Marx and also has created a few of its own: the rapid obsolescence of knowledge, and the extreme vulnerability of such systems to 'guerilla'-type action—be they works to rule at home, or Sino-Vietnamese warfare abroad.

The attempt to explicate science (as distinct from science-based industry) in orthodox Marxist terms is more demanding, a group of Italian physicists make a brave try, but it is not very illuminating for those not sharing the paradigm. The second half of their essay, based more on their personal experience, is more rewarding. By contrast, the less theoretically-orientated analysis of André Gorz provides a comprehensive radical sociology of scientific knowledge. He sees the system of scientific research from the outside, and accordingly can make criticisms that would be difficult for an established research scientist, however rebellious, to express.

For Gorz, all the features of science that render it the preserve of an upper-class minority, are solely to be explained by their social functions. Science itself is effectively defined by formal teaching and diplomas; traditional or self-taught craft skills have no standing against certified expertise. And only those "socially qualified to exercise authority" will succeed in the training system; thereby ensuring that this knowledge is not utilised by the wrong power. But in any event, most of the knowledge of science is alienated and irrelevant to life, in a unique degree. The people are totally excluded, and the experts are fragmented and helpless (and in the case of academic researchers, useless as well). It is then easy for science to be directed to answer some questions and ignore others (Gorz here mentions high technology medicine squeezing out old traditions and communal self-help). Merely changing ownership relations seems to make little difference, so long as knowledge (and the associated power) is hierarchical. Indeed, in passages that recall Rousseau and the Jacobins rather more than Marxism, Gorz rejects *all* science that cannot be shared among 'the people' as their own.

The discussion of 'ideological' conditioning of science starts with fields studied over past years by the Roses: IQ and 'biologism'. Perhaps because of one's prior familiarity, the feeling of "yes, but" increasingly obtrudes on one's reading of the well-argued essays. For example, we are told explicitly that theories linking race and IQ "provide an apparent scientific rationale for the existing social order", almost as if our rulers wanted or called for it. But the directors of our educational system

(surely an area of ideological formation and social control) have quite recently jettisoned the IQ as a means of selection, and this is nowhere mentioned. It is generally much more difficult for a radical critic to explain the virtues of a system than its vices; but to ignore the problem is not productive, nor even consistent with the authors' own standards. I must also remark that in the essay on 'biologism', with its catalogue of horrors of behaviour control from the USA, there is no discussion of the current Soviet conception of schizophrenia as a simple mental disease with obvious behavioural symptoms, including, of course, political deviance.

The really 'soft' natural sciences, such as reproduction technology and 'political ecology', are easy targets for analysis, but the studies here are not trivial demystifications. The real contradictions will not be removed by a reduction to 'class' terms; indeed, traditionalist Marxists fare as badly for their ecological blindness, as do the technical fixers of contraception, for their male chauvinism.

This Marxist approach, however, can really prove its power only in a case where the ideology is *not* apparent, where 'objectivity' seems to reign. Such is the case in physics; and J. M. Levy-Leblond delivers a broadside on that

New Autumn titles

Fossil Animal Remains

Their Preparation and Conservation

A. E. RIXON

This practical manual explains step by step all the techniques used to prepare and conserve fossils from excavation to their use in palaeontological collection, providing a comprehensive guide for conservation students and museum and laboratory trainees

Insects, Hygiene and History

J. R. BUSVINE

Professor Busvine's research into the control of medically important arthropods yields him a rich store of curious information, both scientific and literary-historical. His study of human reactions to ectoparasites shows how the extent of man's curiosity about them provides a continuous commentary on the history of biological science and on the manners of past ages.

Evolution and Consciousness: Human Systems in Transition

Edited by Erich Jantsch and
Conrad H Waddington

One of the first truly transdisciplinary books, this important new work bridges the gap between science and other forms of knowledge. It deals not just with scientific questions but with existential questions which concern all mankind — the meaning of life and the evolutionary significance of human design and action

"... a truly groundbreaking work on the threshold of the advance of knowledge." —*From an advance review by Peter Schwarz, Stanford Research Institute*

noble discipline. Of course, one finds factory research there (as at CERN), the sometimes vicious competition for degraded honours as the Nobel prize and the strange cult whereby scientific eminence is a token of practical wisdom. More than this, the author gets into the subject itself, noting its glorification of brainwork over handwork, the pure over the practical, the 'hard' and abstract over the 'soft' and particular. When this science is taken as the paradigm (as for most of this century), its reinforcing of social and sexual elitism, in the educational system and generally, is very strong. Wisely, the author shies away from discussing the relations of this ideology to the 'truth content' of physics; but for a demonstration of how deeply ideology can penetrate, this essay is a very good start.

When we come to *The Radicalisation of Science* the contradictions in the authors' program appear clearly. The Roses have a delightfully self-critical history of British Society for Social Responsibility in Science and its associated movements; but they would not pretend that this movement ever achieved any numerical strength, nor that it is likely to do so in the foreseeable future. In the most erudite essay in the collection, the American radical geneticists, Lewontin and Levins, grasp

the nettle of the Lysenko episode, which did so much damage to the Marxist movement among scientists after the war. They display the many factors that made Lysenko plausible at first: not merely the crisis in food supply, the institutionalised paranoia about 'wreckers', and the resentment against elite foreign-orientated Mendelian geneticists; but also the harshness and irregularity of the Russian climate, that made 'averages' less meaningful than in milder environments and so required different methods and criteria of adequacy in statistical work. For these authors the essence of the matter was that Lysenkoism was an abortive Cultural Revolution: it went wrong because of the particular causes (and also effects) of Stalinism. This might be interpreted as a cautionary tale for hyper-Left reformers of science; and comparison with earlier populist attempts, as the 'Jacobin science' in the French Revolution and the Paracelsians of the Puritan Revolution, would repay study.

How, then, could the true radicalisation of science be achieved? It is a pity that we are not given a successful case study as from Indo-China or Cuba, where a mainly political approach will have been tried. For otherwise, we are left mainly with the women and the inimitable Joseph Needham. (The moving essay by the American Black scientist tells us more about his problem than about an effective solution.) And quite suddenly, Needham does not seem so eccentric as previously in the company of professing Marxists. Of course, he is still developing philosophically, as young in spirit as ever. Here he takes on a new challenger, the counter-cultural Roszak; and like the great Middle Kingdom itself, absorbs and assimilates him. He does so by moving his own Taoism a bit closer to its mystical, revolutionary tradition.

Given Needham's insights, it is really quite simple: 'our' science (be it capitalist or European), is all *yang* and no *yin*; like our civilisation in general, its maleness is dangerously predominant over its femininity. The women's critique of science fits in perfectly here; one (Couture-Cherki) shows the extent

of discrimination and explicit piggery in French physical science, the other (Stéhélin) hints tantalisingly at a feminine cosmology that would enable women to escape the trap of becoming pseudo-males in order to succeed at male-shaped natural sciences. And if this seems fanciful, we can refer back to the analysis of physics by Levy-Leblond.

Of course, no-one has a recipe for *this* sort of radicalisation of science, at least no-one in the Marxist tradition. But is it really a more forlorn hope than transforming science and society by means of an industrial proletariat? After all, Marx *did* believe that ownership relations were the main fetters on the essentially beneficent forces of production; we now cope both with reactionary 'non-ownership' societies and with socially and environmentally malignant commodity production.

This just about brings us back to the worried male (perhaps a scientist!) who has discovered *Spare Rib*. It also may convey a lesson about social change, which is indicated in several essays here. Regardless of how clear or apparently 'objective' may be one's vision of the social world, one cannot simply ignore one's individuality and, from outside, engineer a solution to its problems. For each of us is part of the problem; and in resolving it we must discover (and perhaps demystify) ourselves. Perhaps the next step forward in the study of ideology '*off/in*' science will come from the full working out of this principle in connection with the accepted public knowledge of the natural world. In the meantime, these essays make a very good start; and the editors and authors may well be among the first to share in the next move of the game.

But when all this is said, where does such a neo-Marxist critique leave science? In getting from today to tomorrow, science has enough to do nowadays just surviving. It always happens that the more radical the analysis, the more irrelevant it is to ordinary experience, and the more useless it is as a guide to everyday practice. But change goes on everywhere frequently accelerating rapidly. If we are to understand the emerging radical insights about the social activity of sciences, in their content and contradictions, we must pay serious and sympathetic attention to those who are first trying to articulate them. For this instruction, even those who disagree deeply with the Roses and their colleagues will be indebted to them. □

Methodologies and myths

R. V. Jones

Method and Appraisal in the Physical Sciences: The Critical Background to Modern Science, 1800–1905. Edited by Colin Howson. Pp vii+344 (Cambridge University: Cambridge and London, September 1976) £10 50.

"THIS volume constitutes the first collected edition of work so far done in illustrating an important new development in the philosophy of science, 'the methodology of research programmes'". So claims the editor of this collection of seven monographs which exemplify and examine the ideas of the late Imre Lakatos (who is the posthumous author of the opening paper) regarding the philosophy of science. Five of the papers deal with selected case histories, three in physics (kinetic theory/thermodynamics, wave theory of light, and relativity) and two in chemistry (oxygen/phlogiston, and Avogadro's hypothesis).

The self-styled 'importance' of the new development may make the reader bridle and he may well ask what a research "program" is. It suggests a deliberate plan by an individual or a group, and it ought therefore to exclude those developments in science where there has been no conscious planning; any attempts by subsequent

philosophers to fit such events into a plan will be falsely based. With these prejudicial observations I have attempted, as an experimenter interested in the history of science, to read the book.

As for the philosophy, there is so much unfamiliar jargon that I can only grasp at clues to determine whether or not it is worth mastering. Lakatos discerns four "logics of discovery", of which one is "methodological falsificationism", and his exposition is strewn with terms of comparable ponderosity. So, rebuffed and bewildered, I have retreated to sample two of the case histories to see how his followers have applied his methods in instances where the language and the events are more familiar to me.

In the course of asking "Why did Einstein's programme supersede Lorentz's", Elie Zahar claims that his particular ideas of how physics may be furthered by translation into mathematics are illustrated by an account given by Peierls of the way in which Maxwell arrived at his famous equations. Although Zahar credits Peierls with this account (1963) it had appeared in various textbooks of physics long before, and—as Peierls himself took pains to state—there is no evidence in Maxwell's writings that the latter thought, consciously or subconsciously, in the way described. Briefly, the invention of the displacement current is credited to a desire by Maxwell to balance one of his equations of the electromagnetic field. But in his original (1864) paper Maxwell himself gave his

own, quite different, line of thought. He said that he assumed that the aether was a medium of "small but real density" capable of being polarised in a similar manner to a material dielectric; and that while polarisation was taking place there was a displacement of charge which "does not amount to a current because when it has attained a certain value it remains constant, but it is the beginning of a current". Peierls discounts this, by saying frankly that "Maxwell arrived at the extra term by using a picture that we do not accept today". But the question is not what Maxwell might have done if he had present-day knowledge, but by what route he in fact arrived at the outstandingly imaginative concept of a displacement current *in vacuo*. Maxwell himself recorded his approach clearly; and this was by physical analogy rather than by mathematical analysis. So, although most of us are aware that mathematics may suggest creative steps in physics, Maxwell's displacement current is not an example, and its history would have to be bent to fit Zahar's philosophy. Perhaps he is not to be blamed unduly for relying on so eminent an authority as Peierls, but he fails to quote the reservation, made by the latter himself, which completely destroys the argument.

I have to emphasise that I have only sampled Zahar's monograph and it would require much effort to treat it in detail; it has 141 footnotes and 82 references. Peter Clark's study of "Atomism Versus Thermodynamics" runs to 244 footnotes and 196 references, and John Worrall's "Thomas Young and Newtonian Optics", 252 footnotes and 83 references. Such assiduity cannot be reviewed at length, but one further sample will illustrate why to me the book is dangerous. It concerns the famous two-slit interference experiment of Thomas Young.

Worrall says: "There are, I claim, sufficiently many suspicious aspects of Young's account of the two-slit case to support the belief that he never performed the experiment"; and "However, as I have said, there is evidence that Young never performed the experiment"; and once again "Moreover, the dearth of details in Young's account makes it seem unlikely that Young ever did successfully perform it, and certain that he did not give sufficient information about the experiment to ensure its repeatability by others".

What are the facts? Worrall makes play of the point that Young did not give a full account of the experiment, which he described only briefly in his course of lectures at the Royal Institution between 1802 and 1806. Worrall says that when Young really did an experiment he usually gave enough

Illustrations taken from *The Game and Play of the Chess* by Jacobus de Cessolis. Pp 174 (Scolar London, September 1976.) £12.50; special edition £30. Facsimile edition of Caxton's translation (printed 1482) of an allegorical work "on human morals and the duties of noblemen", which uses the chess pieces to represent the stations and duties of life. To mark the quincentenary of the establishment of the first printing press in England, the British Library, Great Russell Street, London, has mounted a major exhibition of Caxton's work as printer and publisher (Closing date: January 31, 1977.)

details for others to repeat it. But there are possible explanations for Young not describing the Royal Institution experiment in detail: he was speaking to what Brougham denigrated as "an audience of fashionable ladies", and the two-slit experiment, which is described in the printed version of his Royal Institution lectures, is in no more and no less precise terms than many of the other experiments recorded in the lectures.

Further, Young may not have thought the two-slit experiment sufficiently important to be described in a fully scientific paper, because he had already described an equivalent experiment in his 1803 Bakerian lecture. On that occasion he allowed sunlight to pass through a pin-hole and had inserted a cardboard strip about one-thirtieth of an inch wide in the beam diverging from the pin-hole, so as to obscure the central portion of the beam. In the plane of the card there would be left two patches of light roughly equivalent to what would have passed through two slits with their inner edges separated by the width of the card. He then observed the interference pattern produced by the light passing through these two imaginary slits, and showed that the interference fringes disappeared if one or other was obscured. If, as his Royal Institution lecture suggested, he subsequently used two real slits, he may have thought the experimental modification so trivial that he never troubled to describe it in detail.

Now did or did not Young ever do the experiment with two actual slits? Although he described the experiment, he did not say in so many words that he had performed it, and so we cannot summarily dismiss Worrall's claim. And what I have said so far as an alternative explanation involves as much speculation on my part as the contrary involves on Worrall's. But he goes on to give physical reasons why Young would have found the experiment so difficult to do that he would surely have mentioned the difficulties. Worrall says, for example, "We know, in fact, that if the difference of the paths from the two edges of the source to either of the slits is greater than about $\lambda/4$ the fringes will not in general be observable". The implication is that the pin-hole has to be so small that there will be very little light, and that since Young said that the effects were to be observed on a white card (and not viewed in transmission by an eye-glass, as Fresnel later used) Young would have had so little light that he "never successfully performed the experiment".

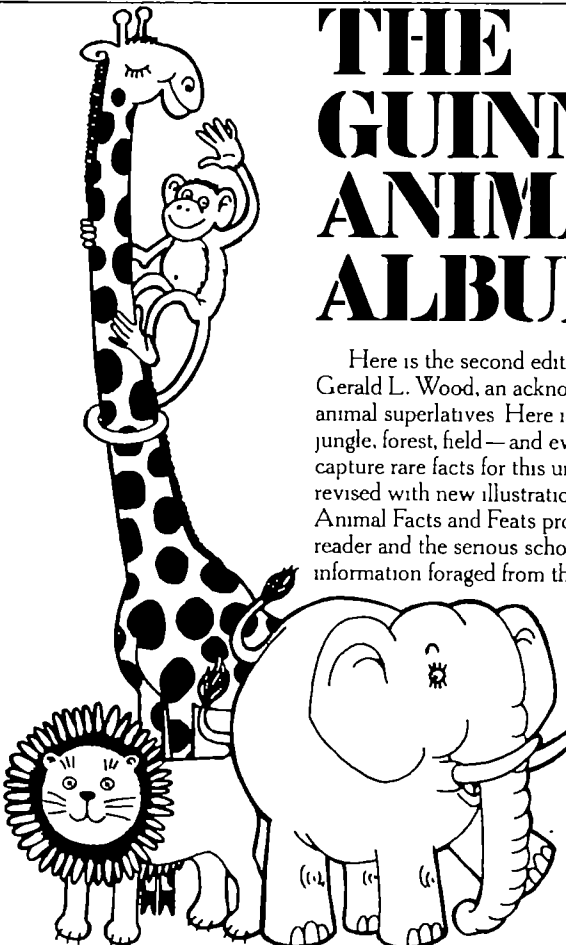

Anyone with a sense of scientific, if not historical, responsibility making such a charge against one of the great

experimenters ought surely to try the experiment himself or to ask a competent experimenter to see whether it is as difficult as he thinks, for it is a singularly easy experiment to check. It merely involves a darkened room, a pin-hole, two adjacent slits scratched in an aluminised mirror, a postcard, and the sun. Stimulated by the need for this review, Dr W. J. Bates and I have made such a check, and no more than a few minutes were necessary to show that Young could have done the experiment very easily. We made a pin-hole in a blind, and if this had had to satisfy the coherence criterion quoted by Worrall, we might indeed have had difficulty in seeing any fringes. But we found that a hole as large as 3 mm in diameter was permissible with a distance to the slits (which were 0.04 mm wide and separated by 0.4 mm) of 120 cm. The fact is that Worrall's coherence criterion, if not completely irrelevant, is far more stringent than the experiment requires—by a factor of at least 40. This makes piquant reading of Worrall's comment: "Young had no clear ideas of what was later called coherence which (had he had them) would have pointed to, and explained the necessity for, a small source at a great distance from the double slit". There are at least two other nonsenses in Worrall's exposition, and Young in

his ignorance was much better off than his twentieth century critic—with the latter's misunderstanding of physical optics. There is enough light with a 1-mm diameter hole not only to see the fringes, but also to see the familiar colours associated with white light fringes.

Young's arguments can sometimes be criticised: he believed that waves could not exert radiation pressure, although Euler had shown that they could, and that light waves were longitudinal. But we can understand why he might not have stressed the double-slit experiment with real slits, even if he had done it, because he considered it easy to do, as we found it easy to repeat from the information in his lecture. Any suggestion that he could not have done it, and did not give enough information for it to be repeated, is therefore irresponsible.

I may have been unfortunate in my sampling, but I can applaud only the last monograph in the book, by Paul Feyerabend, who concludes of the methodology of research programs: "It has not led to a better understanding of science and it is even a hindrance to such a better understanding because of its habit of beclouding facts with sermons and moralising phrases". The book is not completely worthless, in that it is a useful source of reference,

THE GUINNESS ANIMAL ALBUM

Here is the second edition of a fascinating volume by Gerald L. Wood, an acknowledged world authority on animal superlatives. Here is a wide-ranging hunt through jungle, forest, field—and even into pre-history—to capture rare facts for this unique collection. Entirely revised with new illustrations, *The Guinness Book of Animal Facts and Feats* provides both the general reader and the serious scholar with well-indexed information foraged from the world of wild animals.

GUINNESS SUPERLATIVES

and it is at times challenging. But it supremely illustrates the dangers that now beset the history and philosophy of science. Dionysius may have been right in regarding history as philosophy teaching through examples, and the analysis of case histories is therefore worthwhile on this account. But historians and philosophers of science are becoming increasingly involved in talking to one another in a self-propagating language and literature of

their own, and all too many have no working contact with experimental science, where there is no place for assiduous nonsense. Socrates said that philosophy was not for those without experience: and this is no less important for natural philosophy than it is for moral. □

Plasticity and resilience

Freda Newcombe

Early Experience: Myth and Evidence. By A. M. Clarke and A. D. B. Clarke. Pp. x+314. (Open Books: London, 1976.) £3.95. *The Growing Brain: Childhood's Crucial Years.* By John Brierley. Pp. 138. (NFER Publishing: Windsor, 1976.) £3.55.

THESE two books reflect different facets of human growth: early plasticity and enduring resilience. The points of view are reasonable and complementary; the danger is that extracts out of context may be used to bolster overgeneralisations and dogmatic prejudice; and the encouraging aspect is that their authors are searching for the facts—physiological and behavioural—that are necessary for any advance in understanding the complexities of development.

Claims already published about *Early Experience*, ranging from the harm it may do to its "revolutionary implications for the design of education and social policy", obscure its clearly defined brief. The Clarkes have assembled evidence to support a rational hypothesis: that early experiences do not irrevocably determine future development and that "the possibilities for alteration in response to a changing environment remain open for longer than has been commonly accepted" (p18), with the reservation that "this responsiveness decreases in time" (p272). They comment on the inadequacy of received wisdom on child-rearing, they point to the discontinuities in normal development, and the rôle of learning (and—equally important—the possibility of unlearning inappropriate responses); and they note a "remarkable resiliency", a "self-righting tendency" in children, inferred from their physical, intellectual and emotional survival after early years spent in

appalling conditions of isolation and cruelty (see chapters by Davis and Koluchova). Evidence is also drawn from anthropological and animal investigations to show that "the young animal retains an enormous capacity for change in early patterns of behaviour and cognitive competence, especially if the initial environment is seriously altered" (Kagan, p121).

Group studies in the book suggest that the outcome for children initially reared in institutions is related to the adequacy of later placements in other institutions (Skeels) or adoptive families (Tizard and Rees). Children from poor backgrounds may make good progress after relatively late adoption (Kadushin) or institutional care (Lewis; Clarke and Clarke; Reiman). An interesting chapter (Bronfenbrenner) on the so-called "head-start" programs makes the point that the substantial gains shown in the first year tend to fade unless reinforced by follow-up programs and parent participation. The evidence from head-start programs is, however, two-edged. Of more direct impact is the report (Rutter) on parent-child separation, and the significance of genetic and environmental variables. It suggests that the *cause* of separation rather than separation itself may be associated with maladjustment and delinquent behaviour.

The Clarkes have not glossed over the problems of sample, selection and measurement which make quantitative generalisations about child-rearing practices untenable. They are well aware of the constraints on development imposed by constitutional factors; and they do not push their argument to the limit: "there is absolutely no implication that infancy and early childhood are unimportant, only that their long term rôle is by itself very limited" (p272). Negative data, as far as they are aware, do not invalidate a system (p272). By the same token, it is possible that observers have failed to detect subtle changes of language, intelligence, social skills, and personality in children who are at risk in the early years of life. Psychometric tests and questionnaires have their uses and their limits; "the marked

inability to concentrate of many institutional children by the age of five" (p149) is one of the minority notes in this volume that would be interesting to pursue.

It is a pity that some of the authors in the Clarkes' book were recently featured as "the anti-Bowlby team", and that their book has been described as likely to do more harm than good. In turn, the reported suggestion of one of their authors that Bowlby's influence has been "mainly bad" on middle-class mothers is equally inappropriate. It is easy to assign the rôle of spectre in the nursery (*pace* Spock), but that this has perhaps too often been done after somewhat biased interpretations of the maligned experts' texts. And both Bowlby and the present authors have made a positive contribution to the understanding of behaviour. Only those who cling obstinately to a single explanation—the either/or fallacy that clouds so much political and sociological thinking—will adopt a militant stance. The Clarkes' book will be of great interest to those psychologists, clinicians and caseworkers who are concerned with the theory and practise of child-rearing.

DR BRIERLEY'S book, addressed to parents and teachers, summarises work in neuropsychology and developmental and physiological psychology that has a possible bearing on human growth and educational needs. It reflects wide reading in rapidly expanding disciplines and takes on the challenging task of distilling this personal selection into a coherent and feasible view of human development: a brave assignment worthy of Browning's view of man's reach.

Few will quarrel with its main assumption: the child has unique genetic equipment, it is very dependent on the environmental stimulation it receives during the early years of life, and yet it is endowed with a remarkable degree of flexibility and tolerance to stress. The practical implications of this viewpoint are discussed with a plea for an environment rich and varied enough to sustain the diverse needs and talents of human creatures. In contrast, there is little stress on the need for structured training in the early years. In this context, a report in the Clarkes' book that "cognitively structured curricula produced greater gains than play-oriented nursery programs" (Bronfenbrenner, p247) is interesting (a seldom cited and somewhat unfashionable point of view, that might be worth reviving if the percentage of children in the UK with problems in reading, writing and arithmetic is to be reduced).

Given the vast scope of the book,

it would be unreasonable to cavil at details. Inevitably, the selection of experiments will not be approved by all physiological psychologists. Similarly, neuropsychologists may find the functional maps of the brain oversimplified and note that the concept of hemispheric asymmetry of function and the special rôle of the right cerebral hemisphere for *certain* aspects of visual and spatial perception were established long before the study of a small group of patients with callosal sections (p53). Linguists may well be startled by the view that "the remarkable power to speak foreign languages . . . can be explained on the basis of conditioned reflexes" (p 96); and those concerned with brain mechanisms may consider that too much stress has been placed on brain weight at the expense of circuitry and the complexities of modular organisation. The account of physiological

mechanisms and biochemical changes that may underlie the processing and storage of information in the brain is necessarily speculative; and the section on memory and learning is limited to the notion of a "hippocampal taperecorder" (p90), omitting much recent clinical and experimental work in this field.

As a general introduction to the topic, however, the book is a useful, well written and stimulating guide, remarkably free from jargon and pitched at the right level for the readers for whom it was designed. Few would do better or even have the courage to attempt it. □

Representation of meaning

John Morton

Language and Perception. By George A. Miller and Philip N Johnson-Laird. Pp. viii+760. (Cambridge University: Cambridge, London and Melbourne, August 1976.) £12.50.

THIS book is about the representation of meaning. Tired of waiting for linguists to produce a usable semantic theory the authors have started to build a psychological one. The starting point is the perceptual world and its representation in memory. A conceptual theory of memory links this with language. On the one hand we have words and on the other we have ways of testing the perceptual world to find what concepts are appropriate to describe it. In this way we can learn and put what we see or remember into words, or take appropriate action when someone addresses us. In the latter case the sentence is translated into a program which can then be executed appropriately.

Miller and Johnson-Laird illustrate their position with the sentence "Did Lucy bring the dessert?" This is translated into a program which they represent as: find (M(EP), $F(x, y)$) This program will be interpreted as an instruction to search for a particular event in a particular (episodic) memory store. F is a pointer to a particular operator which characterised the meaning of the verb 'BRING'. x and y point to the concepts corresponding to 'LUCY' and 'DESSERT'

respectively. This translation procedure is automatic for the listener who knows English well. He then has the option of answering. This is organised by an executor, which must find the episode and apply the various tests which define BRING: (i) find (domain, COME (agent)) and call it e ; (ii) test (during e , HOLD (agent, object))

These tests can be interpreted in this situation (after the various arguments have been assigned their values) as: (i) find (and label as e) the episode when Lucy came; (ii) find out whether Lucy was then holding the dessert. The operator COME involves further tests which include various perceptual predicates concerning the motion of Lucy; HOLD is itself such a perceptual predicate.

The procedures may fail in a number of ways. the relevant episode may not be found; Lucy might have been carrying something other than dessert. These failures would be interpretable by the executor, who could try alternative ways of answering the question or organise a reply—including that of "Don't know".

They discuss some of the ways in which syntax might influence the translation program, including control instructions such as 'ACHIEVE', which result from commands. And they outline ways in which factors such as intonation, context and intent would influence the processing.

The next problem was that of exploring of lexicon in more detail, having established the kind of machinery the lexicon would be involved in. Initially they attempted to do this using purely perceptual tests in the lexical entries. But that soon became inadequate and they introduced functional information. Thus a table must have a WORK

TOP which is defined not just as being flat—readily testable perceptually—but also it must be "large enough, and rigid enough, so that, if it is supported horizontally at an appropriate height, it will support objects for a person to manipulate with his hands." Such a definition incorporates sensorimotor predicates in its evaluation and the need for analogic prediction. Consideration of speaker as well as hearer necessitated a more flexible approach to the lexicon, and the need to include in the theory some acknowledgement of the relationships between Lexical items led to the idea of core concepts in semantic fields.

The core of FURNITURE is that it assists in accommodating people's bodies and the objects and instruments they use as they engage in eating, sleeping, working, or playing. This core motivates the conditions in a decision table. The conditions are tests with YES/NO answers and the pattern of answers to the conditions leads to particular lexical concepts. Thus for SEAT there are conditions which ask whether the object (1) is for one person only, (2) has a backrest, (3) is upholstered and (4) has legs. If the first two answers are YES then the object must be a CHAIR; with the pattern YNYN it could be a footstool or an ottoman, and a further test or specification would have to be made. The advantage of the decision tables is that they can be used in both ways—from properties to lexical concepts or *vice versa*. Verbs are related together in a slightly different way in this theory, there are core concepts such as TRAVEL, POSSESS, SEE which are then refined in various ways, such as by specifying the manner—to give verbs such as LURCH, OWN and GLIMPSE.

The semantics is not just of language but of the real world as we perceive it; objects, spatial relations, actions, time; and the use of psychological data is more apparent on the perceptual side of their theory than on the language side. The authors seem to make the Whorfian decision to base perception on language—in this case English. All words are related to the perceptual world and all aspects of the perceptual world are related directly to the lexicon-based conceptual structure. What they do not do is create an intermediate level. The decision tables seem to be language specific, and it is not clear how we can think other than verbally. To take a simple example: I feel I can conceptualise separately. we (me, you and him); we (me and you); and we (me and him). The decision table, however, produces only the conditions—the tests of who is included—and the words. The three versions of *we* are separated only in the columns

of the decision table, which are not the right kinds of things to serve as cognitive units. Their decision may have been the right one but I would have liked to see their motivation.

I expect there are going to be lots of flaws in the routines they suggest. I didn't specially look for them but some jumped out at me—such as the requirement, in the definition of LOOK AT, that the back of the eyes, the pupil and the object looked at have to be in line. Not only can you look at someone through a mirror but also out of the corner of one's eye. The former objection may be trivial but the latter looks as though it will require a distinction to be made between the routines used by the looker and by the looked at. This is a game the authors couldn't hope to win first time out. Either they analyse a few concepts into the ground and produce something lacking generality or they attempt to cover enough ground to justify general principles with the risk of getting details wrong.

While their local arguments are coherent, the book as a mass is rather heavy. I get the feeling that they were looking over their shoulders at linguists and philosophers, and in so doing blurred their psychological position. Their final 'Conclusions' chapter, which might have clarified this, reflects rather the "thank god that's over" feeling of the Preface. One little thing which made the book more difficult to read than it need be is the idiosyncratic indexing. They construct lexical entries for scores of words but don't include the words explicitly in the index. As it is, PERSUADE can be found through 'Communication verbs: perlocutionary'; and core concepts in their model, such as 'core concept', have no entry at all.

To obtain a rounded and more leisurely evaluation of this book (without actually reading it, that is) you will have to watch out for reviews in linguistic, philosophical and psychological journals. Each will have different objectives, requirements and criteria, and together they will pick it over as thoroughly as it deserves. At the moment I have no idea how many of the authors' ideas will survive, but I am certain that it will provide a fresh impetus to work in the area. For whatever its technical weaknesses may be, the outstanding merit of the book is to show how difficult the task is by submersion rather than dipping in the big toe. People really interested in the area have no option but to look at it.

John Morton is a member of the scientific staff at the MRC Applied Psychology Unit, Cambridge, UK.

Autumn Books

Astronomy

Magnetohydrodynamics

T G Cowling (*University of Leeds*)

A title in the series of *Monographs on Astronomical Subjects*

A book dealing primarily with the fundamental ideas and principal phenomena of the subject, drawing its examples from problems of the earth's core and extreme outer atmosphere, the sun's magnetic field, and interplanetary and interstellar plasmas. The discussion is limited to continuous fluids.

x + 136 pages illustrated 250 x 155mm
cloth ISBN 0 85274 300 9 £10.00 net

Concise Encyclopedia of Astronomy

A Weigert and H Zimmermann (*University of Jena*)

First published as the *ABC of Astronomy*, this excellent book has been revised and enlarged. It contains about 1500 articles ranging from simple definitions of terms and concepts to lengthy treatments of important matters in astronomy.

532 pages about 200 illustrations
240 x 170mm cloth
ISBN 0 85274 099 9 £9.00 net

Mathematics

The Theory of Graphs

B Andrasfai (*Budapest Technical University*)

Graph theory requires no advanced mathematics but it does encourage lucid thinking. In his introductory text Dr Andrasfai leads his reader from simple exercises and elementary concepts to advanced work in this fascinating branch of new mathematics.

320 pages 264 illustrations 230 x 153mm
cloth ISBN 0 85274 249 5 £15.00 net

Decomposition of Superposed Density Functions

P Medgyessy (*Hungarian Academy of Sciences*)

With applications in spectroscopy, nuclear physics, biology, mathematical statistics and system identification this seemingly theoretical subject has many practical uses. Dr Medgyessy's book covers the recent advances in this rapidly expanding subject.

308 pages 238 x 168mm cloth

Biographical springboard

June Goodfield

Half a Century of Medical Research. Vol. 2: The Program of the Medical Research Council, UK. By A. Landsborough Thompson. (HMSO: London, August 1976.) £10.

THIS is the second of two volumes which together cover half a century of research effort, and form a history of Britain's remarkable and distinguished institution—The Medical Research Council (MRC). The first volume (for review, see *Nature*, 252, 134, 1974) covered the constitutional and organisational aspects of the Council's history and dealt with the intriguing issues of the origins of policy and, "the formulation of those administrative principles" that related to the promotion of medical research. It could have been—should have been—a fascinating book: in the event it is impeccably dull.

This second volume is concerned with the Council's scientific program in detail: once again with the origin of policy and the varied circumstances which led to certain subjects being selected for special support. But now the context is broader for as the MRC itself was expanding over the sixty years in question, so too were the boundaries of the scientific world. So the Council's efforts and achievements must be assessed in terms of the wider international effort in biomedical research.

By any standards the record is most impressive. For measured either by an intuitive feel for fields likely to be significant, or by a balanced stance that recognised the legitimate interests of both the government and the scientific community, serving the one without stifling the other, the record is, on the whole, superb. One can be thankful that, in 1913, the committee that submitted a general scheme of research ignored the narrow interpretation of the phrase—"provision of research"—laid down by considered legal opinion. The National Insurance Act of 1911 appropriated one penny per annum per head of the insured population of Britain, to be allocated from parliamentary funds for "the purpose of research", and the lawyers held that research might well have to be restricted to the diseases of insured persons only. At that time, tuberculosis certainly, but possibly not cancer! But the committee quietly by-passed that

issue and we may thank God for that, for stemming from their general injunction to cover "all researches bearing on health and disease, whether or not such researches have any direct . . . bearing on any particular disease", has flowed such specifics as penicillin, the structure of DNA and the basic mechanisms of cell-mediated immunity.

One must accept that this is essentially a work of compilation. By far the greatest source of material used by the author has been the Council's own annual reports and a variety of scientific papers, reports and documents. These are bound to be bland, objective and reasonably free of human virtue, or vice, alike. So as with the first volume, this is not history as historians know it, for the human content has once more been either ignored or extracted. What has been provided is a valuable series of reference points from which others may start more vital histories.

Nevertheless, there are fascinating insights to be discerned for those who are prepared to weave a passage through the maze of detail. The social picture of Britain we have derived from other sources is intensified by a knowledge of where the early clinical efforts were directed—on tuberculosis, rickets, the hygiene regulations for milk—problems that later society does not face, either because of new knowledge or changed habits.

In the days of quack cancer cures it is salutary to be reminded once again of the human traits of venality and fear; much trouble stemmed in the early days from those who promoted dubious claims for tuberculosis. Then, as now, they "stimulated pressure groups of busybodies, and patients,

anxious to pioneer against the alleged tyranny of the professional closed shop". To set this into the contemporary situation, simply substitute "cancer" for "tuberculosis", "lactrile" from apricot pits, for a "powder with a resolute Zulu name extracted from the root of a South African plant", and the "contemporary medical profession together with the US Food and Drug Administration", for a "professional closed shop".

Even Dr Summerlin and the affair of the painted mouse had its counterpart within the Institute's hallowed walls, for in 1927, virology revealed a seamy side. One investigator claimed to have discovered a virus as the causative agent for disseminated sclerosis; she even prepared a vaccine from cultures which was actually clinically used by certain physicians, even before other scientists had tried to repeat the results. When the results could not be reproduced the scientist was invited to repeat her work under supervision. She then "withdrew from the scene", as the author coyly writes, and it was discovered that she had been using the virus of bovine pleuropneumonia which had been described by the National Institute, and from where she had obtained her cultures.

Plus ça change . . . but things are never quite the same. Science in its achievements has progressed wonderfully even if human beings seem to be much the same. But they are deeply fascinating nevertheless, and I miss them in this volume, just as much as I did in the first. □

June Goodfield is a Visiting Professor at The Rockefeller University, New York.

Fact, fiction and fraud

Michael Stoker

The Patchwork Mouse: Politics and Intrigue in the Campaign to Conquer Cancer. By Joseph Hixson. Pp. x+228. (Anchor/Doubleday: Garden City, New York, 1976). \$7.95.

IN this book Joseph Hixson tells the story of Dr William Summerlin, and much more besides. Summerlin, a dermatologist turned immunologist, claimed that tissue which had been kept in culture could be grafted across transplantation, even species, barriers. But, in 1974, when working at the Sloan-Kettering Institute in New York, he

was caught red (or rather black) handed after using a felt pen to touch up some supposedly successful pigmented skin grafts in white mice. The subsequent enquiry revealed other evidence or de-

Robert Good

liberate misrepresentation to his colleagues. For example, untouched rabbit's eyes had been shown at several meetings as successful corneal transplants.

A nasty little episode no doubt, and pretty awful for those involved, but why should a distinguished science writer bother to write a book about it? After all it is not the first time that a scientist has been caught cheating; and, paradoxically, where fiddling of evidence is the greatest sin, as in scientific research, it also has the least consequence in the long run, since the cheat destroys himself, not science.

The Summerlin incident had special features, however, which must have proved irresistible to Hixson, and which he has exploited with skill and flair. First, the claim itself was of tremendous potential importance, not only for patients waiting for grafts, but for its bearing on immunological theory, based as it is on the classical concepts of Burnet and Medawar. All this is painlessly explained in considerable detail and with the expertise of the good professional journalist. Second, Summerlin, not normally one for rushing into print with detailed articles in scientific journals, is apparently a charming and persuasive speaker, and his transplantation story had received the full treatment from the press and radio networks. Small wonder that the media were not silent when the science writers found they had been caught out. Hixson's often riotous, but always sympathetic, accounts of his colleagues in the press corps are not to be missed, if only for the educational content, which should be recommended reading for graduate students.

Most important, however, in Hixson's view, was Summerlin's relationship with Dr Robert Good, Director of the Sloan-Kettering Research Institute, the largest cancer research establishment in the United States, one of the original triumvirate advising the

President on the great cancer programme and one of the most powerful figures in immunology and cancer research. Good had been intrigued by Summerlin's claims, and brought him to New York in an exalted position, apparently to the disquiet of some of the original senior staff of the Institute, who were inevitably grumbling about a new Director riding roughshod over the existing regime, and pushing on his own ideas, especially on tumour immunology, to the forefront. Good, although a co-author with Summerlin (presumably as his sponsor) had never been directly involved in the work himself, and partly as a result of reports from Summerlin's own staff, had indeed begun to suspect something fishy some months before the ink episode. Summerlin's defence was that he broke down in the face of Good's insatiable demand for significant data (they were certainly needed); and instead of being summarily sacked, as many might believe should follow such dishonesty, he was actually rewarded with one year of terminal sick leave.

The pressures in the Sloan-Kettering, and its special position, thus leads Hixson inevitably to the uneasy power politics of the proposed (and ordained) 'Conquest of Cancer'. Although it is all dealt with historically, and with little explicit statement of the author's personal view, the message which emerges in Hixson's book is clear—that vote-seeking congressmen, anxious administrators and a hungry press, are tempting greedy scientists into exaggerated predictions and claims about cancer, which if not actually as fraudulent as those of Summerlin, may seem so in retrospect to relatives of cancer patients.

The Patchwork Mouse is not written for the usual *Nature* reader, and you have to swallow a colourful narrative style, which may not always be based on direct observation. "Robert Good has shaved and pulled a white turtle neck shirt over his dark, tousled head at an hour when the swinging East Side singles bars have barely closed their doors". How does he know? Perhaps Good gets into his turtle neck feet first. There are also a few errors. For example, cancer as a whole is not commoner in those with defective immunity, only certain rare forms of the disease. The text seems, however, to be generally accurate with careful qualification of statements and quotations whenever required.

This is a fascinating and readable story with compassion for the people involved. Unlike the principal character, Hixson tells it as it is. □

Memorial to cotton research

H. S. Darling

Agricultural Research for Development: The Namulonge Contribution. Edited by M. H. Arnold. Pp. x+353. (Cambridge University: Cambridge, London and New York, August 1976.) £13.

THE Cotton Research Corporation (CRC) was established by Royal Charter in 1921 under its former title of the Empire Cotton-Growing Corporation. For 55 years until it was dissolved in 1976, the CRC played a leading role in research and development in support of the field production of the cotton crop in the anglophone countries of the tropics especially in Africa. From its administrative headquarters in London the CRC maintained a team of thirty to forty carefully selected and trained research workers distributed around the world and renowned alike for their unity of purpose and the consistent high quality of their work. The CRC team was regarded with considerable justification as a *corps d'élite* among the British agricultural scientists who have made such an important contribution to the development of the anglophone territories of the Third World.

The deployment of CRC staff was governed from the outset by two considerations. The first was the need to provide research assistance, often of a trouble-shooting nature, in areas in which increased cotton production was desired. In such cases, CRC workers were posted to government agricultural stations in cotton-growing areas to give specialist support to local research programmes. The second consideration was the need to maintain at least one permanent multidisciplinary research centre under direct CRC control, where long-term work of a fundamental nature could be carried out on problems peculiar to the cotton crop with the object of providing information of relevance throughout the tropics. From 1945 to 1972 this second need was met by the Namulonge Cotton Research Station in Uganda.

As its subtitle indicates, the book under review is concerned with Namulonge and is a composite production from the pens of senior scientists, each a specialist in his own field, formerly on the staff there. Editorial unity has been gently imposed by Dr M. H.

Arnold, the last CRC Director of the station, who is himself a major contributor. The whole provides an excellent description of Namulonge and of its work over the period 1945-72. Sited in the centre of the southern half of Uganda some 35 km north of Kampala, the station covered 900 hectares of reasonably fertile soil, most of which was suitable for field trials and other forms of agricultural research. Established on land leased by the CRC from a Ugandan landlord and built with UK funds, the station was well equipped with laboratories, other research facilities and housing for staff. In 1972 the station was handed over to the Ugandan Government as a going concern some three years before the CRC itself came to the end of its active life.

The meat of the book lies in carefully written yet readable descriptions of research at Namulonge given in chapters 2-8 and comprising two-thirds of the total text. These seven chapters bear the following titles: agrometeorology; soil productivity; crop physiology; entomology; plant pathology; resistance breeding; and plant breeding. They are followed by a chapter of importance on Namulonge farm and a closing chapter on the application of agricultural science to national development. There is also a references and author index and a full subject index.

The accounts of research are always competent and often brilliant. The descriptions of cotton-breeding in chapters 7 and 8 are highly authoritative, embodying as they do cumulative experience of 40 years of work by several generations of CRC geneticists and breeders including men of the standing of J. B. Hutchinson and R. L. Knight. Surprisingly enough, the name of S. C. Harland is conspicuous by its absence! The chapter on Entomology is to be commended for its clear and accurate analyses of complex situations resulting from the sequential incidence of a wide range of pests, and from the interaction of the effects of insect-damage and planting times. Less satisfactory is the chapter on soils and soil productivity where no mention is made of work in Nigeria by B. W. Bache, P. R. Goldsworthy, R. G. Heathcote, D. Lawes and others, which presumably was well known to the Namulonge team. This West African research preceded and paved the way for the agronomic advances described by the Ugandan workers in the late 1960s and early 1970s.

For all its general scientific competence and its areas of technical brilliance this book is less than satisfactory in that it fails to ask, let alone seek to answer, at least three important questions. First: why was Namulonge

chosen as a site for basic research on cotton-growing? Second: why does no thought seem to have been given in the planning of work programs to research on the human factors that dominate cotton production? Third: why is so little mention made of plans for training local research workers to replace European staff when (as has already happened) CRC control came to an end? These questions are of major significance.

The choice of Namulonge was made when the reviewer was working as an agricultural research worker in the then Ugandan Protectorate Department of Agriculture. It seemed obvious that the site was atypical of areas suited to cotton production in that it was too cold and was unsatisfactory in respect of rainfall distribution. It has long since been accepted by Ugandan farmers that the area is agronomically suited to the growth of robusta coffee and plantains rather than cotton. The farming systems laboriously worked out by the Namulonge staff, although successful in themselves for making the best of cotton-growing in local conditions, are largely irrelevant to local agriculture and are to that extent a waste of effort.

Successful cotton-growing in the near-subsistence conditions that obtain in Ugandan agriculture, and indeed throughout much of tropical Africa, depends on plentiful supplies of human labour. Any research program aimed at increasing cotton production in developing countries should recognise the importance of human factors and, where these factors are not clearly understood, should seek to define and elucidate them. Technical developments conceived without relevance to human considerations often fail to be adopted. A classic example of this is the question of planting dates for cotton in Uganda. Here scientific evidence indicated that early planting was essential for best results in terms of yield. All human experience showed that local farmers found such early planting to be impracticable in the context of their overall farming systems. In the view of the British research worker, trained in the natural sciences, it was essential that early planting be advocated as official policy and the resulting impasse has dominated local cotton-growing policy for many years!

Namulonge, in common with many other British-based agricultural research stations, failed to appreciate the need for research inputs from economists and rural sociologists in the interdisciplinary mix of the station program as a whole. The failure is apparent in the last chapter of the book on the application of agricultural science to national development, which is too vague to attract attention or

inspire confidence. The workers at Namulonge clearly felt confident of their ability to advise on growing cotton. It is equally clear that they had few ideas as to the role of cotton production in the Ugandan economy.

The apparent lack of attention to the training of African staff is surprising. The upgrading in 1948 of Makerere College at Kampala to university status enjoying special relationship with London University followed closely on the establishment of Namulonge in 1945. The first director at Namulonge, Sir Joseph Hutchinson, was Chairman of the Council of Makerere College from 1953 to 1957, and played an important role in the development of the excellent Faculty of Agriculture there, including the establishment of its outstation at Kabanyolo. Namulonge's staff were

encouraged to lecture in the Faculty. Yet in spite of these close ties between Namulonge and Makerere, little or no thought seems to have been given to using the new university to build up a body of local scientific expertise in cotton research.

This grave omission was unfortunately a major weakness of the CRC as a whole. The dissolution of the Corporation in 1976 has consequently meant that with the disappearance of the London headquarters, little in the way of research staff and human assets persist in a recognisable form. A proud ship has sunk virtually without trace and the book under review can almost be regarded as its memorial tablet. □

Dr Darling is Principal of Wye College, University of London, UK.

Self-reliant development

C. H. G. Oldham

Beginnings of Brazilian Science: Oswaldo Cruz, Medical Research and Policy, 1890-1920. By Nancy Stepan. Pp. xi+225. (Science History: New York, June 1976.) \$12.95.

EFFORTS to build up local research capabilities in many developing countries over the past two decades have frequently been frustrated by the lack of local demand for the results of this research. As a result, policy makers in these countries are currently preoccupied with measures to stimulate demand, and to make science more relevant to national needs. This is proving to be no easy task since the science system has grown in isolation from the productive system and the forging of links is exceedingly difficult.

Nancy Stepan's excellent book, *The Beginnings of Brazilian Science*, shows how governments in the developing world might have been saved a good deal of unnecessary expense and anguish had they known of, and heeded the lessons which were to be learnt from the growth of biomedical science in the late nineteenth and early twentieth centuries in Brazil.

Most of Professor Stepan's book, and certainly the best part of it, is devoted to a case study of the Oswaldo Cruz Institute in Rio de Janeiro. This Institute was initially established in 1900 to produce yellow fever serum but grew into an excellent scientific centre covering the entire spectrum of scien-

Oswaldo Cruz

tific activities—basic research, development, staff training and even production. It had an international reputation and was staffed entirely by Brazilian scientists. Those looking for an example of self-reliant development in science in the third world would have to search hard to find a better example than the Oswaldo Cruz Institute. To emphasise the positive lessons which she thinks are to be learnt from the history of this Institute, Professor Stepan contrasts its success with the failure of the Bacteriological Institute of Sao Paulo, established at roughly the same time. The story of the Sao Paulo Institute, although useful for comparative purposes, palls in comparison with the exciting and dramatic success of its Rio de Janeiro rival.

Professor Stepan clearly shows that the success of the Oswaldo Cruz Institute owes a great deal to the happy coincidence of the right people being brought together at the right time and the right place to meet a particular need. The need was particularly urgent. Brazil, at the turn of the century, had

most of the physical ingredients required for the development of a prosperous and wealthy nation. The main drawback was its extremely unhealthy climate. Rio de Janeiro was largely avoided by foreign visitors because of its foul reputation for disease. Epidemics of yellow fever, bubonic plague and other tropical diseases caused the deaths of thousands of people each year. The need for a solution to these epidemics was apparent to the public and politicians alike. There was a 'demand' for the results of scientific research.

Fortunately the time was also ripe scientifically for a biomedical research institute established in a developing country to be able to make internationally significant contributions, and at the same time solve a pressing national need. Had the politicians provided the funds thirty years earlier, it would have been too soon. But, in the latter part of the nineteenth century, due in large measure to the work of the Pasteur Institute in Paris, an understanding of the bacteriological origins of many diseases had been developed and the whole field of immunology had been opened up. By 1900, when the Institute was founded, there was a real opportunity for major advances to be made in bacteriology; an opportunity which the Brazilian scientists were not slow to exploit not only for the benefit of the Brazilian people, but also for the benefit of science as a whole.

The real hero of the story is Oswaldo Cruz himself. He was trained as a doctor and went to study at the Pasteur Institute in Paris. He returned to Brazil and, against very considerable political and public opposition, converted an Institute initially established solely to manufacture serum, into one of the world's leading biomedical centres. His approach was almost the exact opposite of the one normally taken by developing countries today. Instead of starting with research and then trying to find some use for the results, Cruz began with a need, and with a solution to a part of that need—the manufacture of yellow fever serum. He then worked from this to applied research and eventually basic research. This distinction between basic and applied research, however, does not seem to have been one which bothered those Brazilian scientists working at the Oswaldo Cruz Institute. For them there was a job to be done, and if this job required advancing the frontiers of science, this was part and parcel of the job. If on the other hand all that was required was some simple adaptive work in development, then this too was carried out. The Sao Paulo Institute never developed the same range of scientific

activities and, according to Nancy Stepan's analysis, suffered as a consequence.

The book is a fascinating story of the interplay between science, politics and development as they relate to the growth and utilisation of the biomedical sciences in Brazil in the first three decades of the twentieth century. It is marred only by an over-ambitious title (the book only treats some aspects of the biomedical sciences, and not, as it implies, science as a whole), and by an over-simplistic final chapter on the science policy problems of developing countries. There are lessons to be learned from the experience of successful and unsuccessful institutions, and Professor Stepan is right in suggesting

that some of the lessons to be learned from the Oswaldo Cruz Institute are as valid today as they were in the early twentieth century. The times, international relationships, and local political situations have all changed, and Nancy Stepan probably exaggerates the extent to which the lessons have relevance for policy makers today. Nevertheless it is a good book, well researched, and is highly recommended to anyone interested in the broader policy implications of biomedical research, public health, Brazil, and development. □

Dr Oldham is Deputy Director of the Science Policy Research Unit, University of Sussex, UK.

Horological insights

A. A. Treherne

The Lost Science of John "Longitude" Harrison. By W. S. Laycock. Pp.159. (Brant: Ashford, Kent, 1976.) £18.75; \$45.75.

It is fitting that in this year, which marks the bicentenary of John Harrison's death, a book should be published which establishes clearly his contribution to science, and in particular to the science of horology. Even if the reader cannot follow the author in believing that Harrison's contributions to the science (as distinct from the practice) of horology surpass those of even Huygens, the author does establish beyond reasonable doubt that Harrison deserves more than the standard, cursory mention in the physics textbooks for his grid-iron pendulum—a remarkable achievement in itself which is, perhaps, for the first time adequately treated by the present author.

Harrison's contemporaries could never quite bring themselves to believe that a man without the standard academic credentials or any formal horological training could make significant contributions to horological science. Hence the reluctance of the Board of Longitude to award to Harrison the full £20,000 prize offered by the British Government for a solution to the problem of determining longitude at sea, even though during the sea trial of 1761 his 'sea clock' performed well within the limits laid down. Harrison's unorthodox ideas seemed perverse or even absurd in the light of the established wisdom of his time, and in spite of his practical successes few made any attempt to understand the principles behind his timekeepers,

John Harrison

Photo: Science Museum, London, UK

ignoring his published writings as the polemical abuse of a frustrated man. Later historians of science have even less excuse than Harrison's contemporaries for not recognising his successes as arising from the application of scientific method and principles, and for not seeing his work as a clear and natural continuation of the work of Huygens. It is refreshing to find the case so well argued in this book.

The unconventional methods which Harrison adopts are convincingly analysed and justified by the author, again perhaps for the first time. The interdependence of his ideas, and the important role of his remarkable achievement in completely eliminating the need for lubricants, emerge especially clearly; underlining the impossibility of making sense of these ideas if they are considered in isolation, as they often have been in the past. In fact the author not only argues that there are good scientific grounds for Harrison's apparently fantastic claim that it would be possible to make a clock according to his principles with a rate of 2 or 3 yr^{-1} , he also outlines a programme, already begun, to construct a pair of regulators based on Harrison's ideas, in order to put the claim to the test.

Harrison's writings are by no means easy to interpret, as is witnessed by the

fact that no convincing interpretation had previously been offered. What we have in this book is an ingenious but coherent interpretation which, in spite of the necessity for a good deal of imaginative reconstruction and speculation, is, in broad terms, convincing. Moreover, the analysis is always stimulating and could hardly fail to reveal many new insights. I have two main regrets. First, the exorbitant price of the book. At this price one might have expected facsimile reproductions or transcriptions of Harrison's texts as well, which would largely have nullified my second concern: that it is not always easy or even possible to tell from the book alone what is in Harrison's texts and what is speculation or

reconstruction. There are some mistakes and misprints, which most readers will have no trouble in spotting and correcting, but which would prove confusing to a reader with little scientific background.

This book is an important contribution to horology and to the history of science. The general reader, who will require only a very elementary background in mathematics and physics to follow the arguments, will also find it fascinating and stimulating. If it does not sell well, it will be because of the price rather than the content. □

Alan Treherne is a Lecturer in Mathematics and Philosophy at the University of Keele, UK.

Ecology of plankton

G. E. Fogg

Marine Plankton Ecology. By Paul Bougis. Pp. ix+355. North Holland: Amsterdam and Oxford; American Elsevier: New York, 1976.) Dfl.130; \$49.95.

In some ways the ecology of plankton may be simpler than that of terrestrial communities. For most purposes there is only one phase to deal with and the organisms are generally smaller and less complicated than those on land. But apart from the inconvenience, expense and limitations of working at sea, the marine plankton ecologist has the difficulties of investigating events, following each other much more rapidly than in terrestrial situations and in an ever-shifting medium, which may be directly related to others that have taken place thousands of miles away. It is only comparatively recently that the resources needed to deal, even inadequately, with this situation have become available and the writers of textbooks are only just beginning to catch up.

Professor Bougis, who is Director of the Zoological Station at Villefranche sur Mer, has, however, produced an admirable and comprehensive account of this rapidly developing subject. He deals with phytoplankton and zooplankton equally, and with each he begins with a necessarily brief survey of the systematics of the amazing variety of organisms concerned.

For the phytoplankton he devotes chapters to the factors affecting photosynthesis, the nitrogen and phosphorus cycles, other nutrient elements and organic growth factors, enumeration and periodicity, and primary produc-

tivity. For the zooplankton he gives accounts of quantitative studies and distribution, vertical distribution and diurnal migration, nutrition, metabolism and energy conversion, and secondary production.

A final chapter considers the place of plankton in the marine ecosystem, touching on its economic importance and possible exploitation. Appendices deal with such diverse topics as the derivation of the Sverdrup equation defining the conditions required for the spring outburst of phytoplankton and the design and construction of plankton nets—information which is not readily obtainable from other textbooks.

With such a broad canvas it is inevitable that some areas should not be as well covered as others and one such is the topic of phytoplankton buoyancy, which is treated simply as a matter of cells remaining afloat in the illuminated surface waters. The possible value of sinking as a means of increasing nutrient uptake, its interaction with wind-induced Langmuir circulation (which is mentioned in relation to zooplankton distribution only), and the possible role of differential rates of sedimentation in determining species succession, are not considered.

The book is well illustrated and the translator has done an excellent job. There is, however, the increasingly common mistake about the plural of flagellum; fluorescence and luminescence are confused; and a unicellular film of ferric hydroxide is referred to when, presumably, a monomolecular film was in mind. There are also quite a few errors that have escaped the proof-reader. Nevertheless, these are minor matters and the book will undoubtedly be most useful to students, teachers and research workers in marine biology who have access to a library that can afford to buy it. □

G. E. Fogg, FRS, is Professor of Marine Biology at University College, North Wales, Bangor, UK.

Adaptation to Environment

Essays on the Physiology of Marine Animals

Edited by

R C NEWELL

University of Odense, Denmark

This book discusses in detail the special adaptations of marine organisms to the particular environmental conditions which they are likely to encounter in the natural habitat.

It covers not only the recent experimental work in this field, but also gives an overall picture of the conceptual framework which underlies it. The term 'physiology' has been interpreted in its widest sense to include all aspects of the functioning of the organism, from the behaviour of animals to the mode of function of enzymes.

A valuable source of information on zoology, physiology and marine ecology, this book will also prove an indispensable reference work for all libraries in this field.

1976. 554 pages. £25.00.

Light and Plant Development

H SMITH

University of Nottingham

This volume provides a fully comprehensive and up-to-date summary of the control by light of the growth and development of higher plants. It presents the proceedings of the 22nd Nottingham Easter School in Agricultural Science, at which specialists from science, commerce, industry and practical agriculture discussed the important question of Light and Plant Development.

This book will assist crop scientists to come to grips with a topic which is still almost totally studied at the fundamental level, but which nevertheless has great potential importance for crop production.

1976. 528 pages. £15.00.

Too little, too late

H. I. S. Thirlaway

Nuclear Explosions and Earthquakes: The Parted Veil. By Bruce A. Bolt. Pp. xxi+309. (Freeman: San Francisco and Reading, March 1976.) £6.

AFTER the Soviets had unexpectedly broken the moratorium on nuclear tests in 1961, the distinguished owner of this journal (Harold Macmillan) was said to have asked his advisors to show cause why his Government should continue to support seismological research for a test ban; after all was not the UK also free of serious earthquakes? Happily the advice was convincing, the work continued and, according to Professor Bolt, to some effect in a country which had lost its impetus for experimental seismology after John Milne and his contemporaries.

I was reminded of this anecdote by the author's surprise that seismology in aseismic Sweden should be so well supported. It is good that it is because, like the Shields which are seismologically exploited by the Commonwealth countries, Sweden is as near perfect a receptor for seismic waves as one could hope to find—Uppsala was well known for its overestimates of the seismic yields of underground explosions—and in spite of such sites the technical reason why there is no ban on nuclear tests is because the threshold of seismic detection is still rather too high to deter cheating. The fact that places where the seismic transmission properties and ambient noise might be good enough for seismic monitoring of a comprehensive ban on tests are unlikely to be found is not made too clear by Professor Bolt. This means that as long as the possibility of secret tests is a cause for concern, previously unacceptable threshold treaties, like that of the new Soviet-American agreement, must suffice. The author concludes: "the veil across the future of history of civilisation has not been parted".

Nonetheless, seismologists were given every encouragement and opportunity to make a significant contribution to the unveiling; and in describing how they failed this new book by Professor Bolt gives the lay reader a broad and well balanced insight on a many-sided problem.

The basic mechanisms and effects of nuclear explosions and earthquakes, the

way in which the Earth's interior structure and the seismograph modifies the relatively simple seismic wave radiations from these sources, are explained in the first four chapters. We are given an inkling of the confusion which is to follow, but at first all seemed straightforward to the geophysicists from East and West who gathered in Geneva in the summer of 1958 to examine the possibility of monitoring compliance with a treaty to ban nuclear tests. Ironically, the weapon tests which were to deny some of their predictions had already been planned for the autumn; only a month or two after the publication of their report describing how 5 kton or more could be reliably monitored, American seismologists experimentally demonstrated that there would be a great deal of doubt about underground explosions of as much as 20 kton and a few months after that, American physicists showed (theoretically) how to convert a megaton to a few seismic kilotons by detonating in a large enough hole in the ground. That it had to be an unbelievably large hole was irrelevant; the damage was done, in the next three years the opportunity to change the course of affairs (whether for good is another question) passed and the ensuing decade has been devoted to the founding of forensic seismology.

In the end it has turned out that the 1958 experts were not so far wrong, on average, in their 'guesstimate' of 5 kton; seismic waves from yields of this order (as reported by the Soviets) have been recorded on western seismographs with disarming clarity. The trouble is that signals from Nevada are not so well received and it is on Nevada Test Site experience that the Earth is calibrated in terms of seismic magnitude to kilotons of explosive. Geophysicists have been slow to accept that the property of the upper mantle to absorb seismic wave energy varies widely according to the tectonic history of the region. For policing a test ban, it is the behaviour of explosions in regions of high attenuation which determines the threshold at which compliance with a test ban can be guaranteed.

Together with an overestimate in the number of earthquakes of a given size to be expected each year (an error which was rectified in a little remembered US Atomic Energy Commission announcement in July 1962), the existence of unknown, highly attenuating structures was the fundamental source of the early confusion. Professor Bolt takes the next three chapters to describe the results, in the course of which he outlines the contributions of the USA, the Soviet Union and the UK, and of Australia, Canada, China,

France, Japan and Sweden. The Berkner Panel Report outlined the needs in the USA and a curiosity of this report is that its principal contributor was John Gerrard, a product of Professor Bullard's Cambridge department which was to play a useful role in the UK's own contribution.

At the time Bolt completed his book, the prime importance of lateral variations in the upper mantle had not been established, nor had seismogram modelling and the refined aspects of broad band seismology been confirmed as techniques for discriminating between seismic sources and for revealing some methods for testing in secrecy; it says much for the still vigorous development of forensic seismology that Professor Bolt's book is already out of date.

The last three chapters are devoted to accounts of spin-off from the development of nuclear weapons. These include: nuclear engineering for which Professor Bolt is an enthusiast in the face of counter arguments that it is not realistic to seek test bans and non-proliferation of nuclear weapons with, at the same time, freedom to engineer with nuclear explosions, the environmental consequences on people, animals and on earthquakes, the controversies about which were initiated by the megaton sized tests in Nevada and Amchitka Island and, finally, the discoveries about the interior of the Earth which have been made possible because the hypocentre, origin time and size (all unknown quantities for earthquakes) can be measured with great accuracy for nuclear explosions. These discoveries are grouped in the chapter on seismology and nuclear politics on the dubious grounds that politics prevents the free exploitation of large explosions in the interests of seismology.

The book is equipped with appendices giving incomplete lists of nuclear tests by the USA, the Soviet Union, the UK, France and China, and the full text of the 1963 Test Ban Treaty. It is prefaced by a helpful chronology on the principal nuclear and seismological events beginning with Trinity (the first test of all) and ending with the first underground test by France in the south-west Pacific. To students of the test ban problem this French test may represent another gain for the 1963 treaty in spite of non-adherence to it by France. Professor Bolt uses boxes to enclose the more technical sidelines and thereby neatly maintains the well written flow of the text without interruption. □

Oil shale

R. C. Selley

Oil Shale. (Developments in Petroleum Science, 5.) Edited by Teh Fu Yen and George V. Chilingarian. Pp. xi+292. (Elsevier Scientific: Amsterdam, Oxford and New York, 1976.) Dfl.90; \$34.75.

OIL SHALE is a fine-grained organic-rich sedimentary rock which releases crude oil when heated. The industrial extraction of oil from shale began in Scotland in 1862, but at the present time the oil shale industry is moribund in the UK. (A review of British oil shales has been given in a recent paper published by the Department of Energy.)

Over much of the Western World the oil shale industry was important in the past, and will be so in the future, but is dormant at the present time. It is currently practised, however, in the USSR and China. One is reminded of the White Queen's rule. 'Jam tomorrow and jam yesterday-but never jam today' (Carroll, *Alice through the Looking Glass*, Macmillan, 1871).

The world's resources of oil shale may contain some 30×10^{12} barrels of oil, only 2% of which is available for present-day commercial exploitation. This figure is controlled by two factors: the price of crude oil and extraction technology.

The conventional method of extraction necessitates mining the shale and distilling off its oil by retorting above ground. Subsurface *in situ* retorting, aided by explosive fracturing and fluid injection, is still in the experimental stage. So too are biochemical extraction methods currently under investigation at the University of California.

Due to recent advances in organic geochemistry the composition and molecular structure of oil shale hydrocarbons are well known. Similarly the geographical distribution and the geological factors which control the formation of oil shales are well documented. All that is needed to revive the oil shale industry is either a further increase in the price of crude oil, or a major breakthrough in the technology of extracting oil from oil shales.

It is a cliché of our time to say that oil is too precious to burn. It should be used only as the foundation of the petrochemical industry, never as an energy resource. Nonetheless, if nuclear, geothermal or any of the other energy sources currently under review fail to supply the demand then oil shales may become very important.

Oil Shale provides a useful review

of current knowledge of many aspects of oil shales. The book consists of twelve chapters edited by T. F. Yen, Associate Professor in the Department of Chemical Engineering in the University of Southern California, and G. V. Chilingarian, Professor, His Imperial Majesty Shahanshah Arya Mehr Chair of Petroleum Engineering, in the same university.

It is true to say that the University of Southern California is the intellectual font of the book, providing a third of the sixteen contributing authors. The geological core of the book is undoubtedly the Green River oil shale, which, according to the index, is mentioned on 66 pages of the 266 pages of text.

Nonetheless, the book covers the field well. It begins with a brief review of the topic. This is followed by an account of the geological setting of oil shales and their geographical distribution. The latter is displayed in a series of maps showing the distribution of oil shales during different geological periods. This could have been greatly improved had the data also been tabulated so that the reader could find the literature source for every oil shale located on the maps.

An account of the origin and formation of oil shale follows, and is succeeded by a chapter on the origin and characteristics of the Green River oil shale. This Tertiary lagoonal deposit covers large areas of the states of Colorado, Utah and Wyoming, and contains some 80×10^{12} barrels of oil (recoverable by existing technology), representing 15 years reserves of crude for the USA at the 1973 consumption level.

The following chapter, on the mineralogy of oil shales, in point of fact contains a fuller account of the geology, as well as the composition, of the Green River oil shales, than that which precedes it. Succeeding chapters review retorting technology, well-logging techniques, environmental implications (of course) and the history of oil shale research over the past 30 years.

Considered overall, therefore, this book provides an important and comprehensive corpus of up-to-date information on the geology, chemistry and extractive technology of oil shale, which will be of interest to geologists, chemical engineers, government officials and other assorted doom-watchers. In common with most books from this publisher its price of about £20 (at today's rate) puts it beyond the reach of everyone except pop stars and oil sheiks. □

IMAGERY-REMOTE SENSING INTERPRETATION (JIRSI)

Bi-monthly

*Subscription UK £34, elsewhere US \$64

Few international journals cover all aspects of imagery and remote sensing. This journal, while covering most topics of long-range imagery-remote sensing, will concentrate on the often neglected interpretation aspects of fields other journals seldom touch. JIRSI will include meteorology, climatology, oceanography, hydrology (air/water remote sampling), air chemistry, geophysics, geology (particularly seismic/volcanic monitoring), geochemistry, natural disaster investigations, image transmissions from planetary, lunar and solar probes and manned missions, satellite/airborne tracking-optical imaging systems and thermal imagery, military applications in peace and war, aerial and underwater archaeology, instrumentation and films. JIRSI will include original research articles and reviews and will carry advertising, product information, news, personality interviews and stereoscopic pictures.

IMAGERY-REMOTE SENSING ABSTRACTS (JIRSA)

Bi-monthly

*Subscription UK £78, elsewhere US \$148

Covers the same fields as JIRSI. 6000 abstracts in over 1000 pages will be the initial output. As close-range imagery/photogrammetry is not being incorporated into JIRSA a separate abstracts journal is being planned to specially cover these disciplines.

CLOSE-RANGE IMAGERY AND PHOTOGRAMMETRY — INDUSTRIAL AND ARCHITECTURAL APPLICATIONS

Quarterly

*Subscription UK £24, elsewhere US \$45

The first truly international journals to cover specifically all aspects of close-range imagery and photogrammetry. Contents will include original research and review articles, application reports, news, R and D surveys, product information, letters and personality interviews.

The journal on industrial and architectural applications will also include information covering topics on micro-range and non-conventional imagery coherent optical methods, three-dimensional ultrasonic and magnetic projections, TV and digital imaging systems, Moiré techniques, moving-object analysis, from high-speed ballistics/aerodynamics to structural creep/deformation.

CLOSE-RANGE IMAGERY AND PHOTOGRAMMETRY — BIOMEDICAL APPLICATIONS

Quarterly

*Subscription UK £24 elsewhere US \$45

This journal will cover all aspects of biomedical (biostereometric) applications. The field also includes stereometric X-ray analysis, scanning electron microscopy, acoustic holography, thermal imagery.

*Special discounts available

5% for advance payment of any subscription, further 10% for pre-payment of 3 years subscription, additional 10% when 2 or more journals are purchased.

Friendly persuasion on the energy crisis

John Chesshire

The Poverty of Power: Energy and the Economic Crisis. By Barry Commoner. Pp. 314. (Knopf: New York, 1976) \$10.

ALTHOUGH the world may be experiencing signs of an imminent or longer term shortage of energy, there is certainly no shortage of those prepared to write about it. This makes Barry Commoner's latest book all the more welcome because of its refreshingly different approach to energy problems. Although by training a biologist, Commoner uses the physicist's tools (the First and Second Laws of Thermodynamics and the concept of entropy) in a fluent manner to reach the apparently simple, yet powerful, conclusion that "energy is efficiently used when the quality of the source is matched to the quality demanded by the task".

The book's coverage is restricted to the USA, which accounts for over 30% of world commercial energy use, and comprises chapters on the major fossil fuels, nuclear power, solar energy sources, the energy demand sectors and the increasing capital intensity of additional conventional energy supplies.

Although the First Law of Thermodynamics has long been used to assess the efficiency of energy use, it is only since the quintupling of oil prices after October 1973 that energy studies using the Second Law have been widely undertaken. Such studies have revealed that in many instances efficiencies measured according to the precepts of the Second Law are ten times lower than the better-known First Law efficiencies. For example, the First Law efficiency of typical oil-based domestic central heating is 60%, whereas its Second Law efficiency is only about 8%. The installation of a heat-pump system, however, can raise this above 20%.

In his examination of the conflicting evidence on world fossil fuel reserves Commoner is highly sceptical of the value of estimates at present widely agreed. In the case of assessments of US crude oil reserves Commoner argues that "the declining rate of oil discovery per year is a result of company decisions to cut back on exploration efforts rather than on the

depletion of accessible oil deposits". The low economic returns from exploration in the USA have led to the increasing multinationalism of the US petroleum majors seeking lower cost (and higher profit) sources in the Middle East and elsewhere. Nevertheless, despite his optimism regarding the potential size of US and world reserves, Commoner argues that the physical fact of exhaustion, even if delayed by potentially greater resources, is reason enough to plan for the transition from the present heavy dependence on oil to renewable energy sources.

Although Commoner systematically reviews many of these benign energy sources he seems most committed in his discussion of the many issues raised by the growing utilisation of nuclear power. The Atoms for Peace program launched by Eisenhower in 1953 ushered in the widespread harnessing of nuclear power for civilian purposes, but its earlier, war-time history inevitably resulted in the nuclear power industry being a potentially explosive mixture of the civilian and military.

The economic structure of the US nuclear industry is a complex web of public and private enterprise: research and development are largely government funded; uranium mining, milling and conversion are privately funded; fuel enrichment is carried out in government-owned plants, fuel fabrication privately; commercial reactors are owned and operated by private utilities with substantial government supervision (for example, licensing and inspection), whereas all the proposed waste disposal schemes will be government controlled. In addition, since nuclear power is the only civilian technology that the insurance market is unwilling to underwrite, the Price-Anderson Act ensures substantial state settlements in the event of claims arising from a nuclear accident.

Commoner's concern with the specific technological difficulties and dangers associated with fast breeder reactors and the apparent lack of progress to date on operational long-term waste storage and disposal facilities—"a sign both of commendable caution and inadequate work"—is all the more topical given the recent Royal Commission Report on *Nuclear Power and the Environment*. Although confessing his unfamiliarity with economics, he presents a strong case based on the differential paths of increases in real capital costs and fossil fuel prices, to reveal "the likelihood that the entire nuclear program is headed for extinction". I am not totally convinced by this argument, but it is certainly the case that faced with increasingly politicised debate and

opposition to nuclear power—namely, the Swedish election and the Californian referendum—competing claims on restricted public expenditure and the energy research and development budget, rising capital costs, greater environmental safeguards, and downturns in traditionally exponential electricity growth rates, proponents of nuclear power are facing a major reassessment of its future role

In conclusion, Commoner is a persuasive commentator and despite

his strong environmentalist bias and support for solar energy, agrees that the so-called energy gap will not be "swept away in a flood of sunlight". One minor complaint: for a book which is inevitably quantitative, there are no tables or charts to ease the exposition □

Energy supply and demand

Peter Chapman

Potential Energy An Analysis of World Energy Technology. By Michael Kenward. Pp. x+227 (Cambridge University. Cambridge, London and New York, September 1976) Hardcover £6.20; papercover £2.80.

ENERGY research and development is one of the few fields of inquiry that enjoys a steady growth in its level of financing, perhaps more so in the USA than in the UK. Over the past two and a half years Mike Kenward has charted the ups and downs, the fashions and flops in energy research and development in the bi-weekly 'Energy File' in *New Scientist*. He has now put together a large part of this material in *Potential Energy* which claims to be an "analysis of world energy technology". The review of energy supply options is certainly comprehensive, from solar to nuclear fusion through oil, coal, gas, fission, wind and waves. For anyone not familiar with the range of developments in these fields this book is certainly a useful starting point, but only a starting point.

There are two major defects in this book. The first is that Kenward studiously avoids trying to assess the relative merits and disadvantages of the energy technologies discussed. Occasionally we catch a glimpse of what the author's opinions are: "as far as nuclear research and development goes it is doubtful if even more spending is justified". But by and large he merely describes the technology and describes other people's reactions to the problems. This journalistic style was appropriate for a magazine feature on energy, but leaves the reader of the book in a policy vacuum. This is characterised by the platitudinous and obvious conclusion to the book which points to the twin dangers of "putting all our eggs in one basket only to discover there is a hole in the bottom"

and spreading research and development funds "so widely that no energy technology receives enough support to prove itself". Since this was, and remains, the obvious problem in formulating an energy research and development policy it seems a shame that nowhere does Kenward address himself to the problem.

A more glaring defect in Kenward's treatment of energy research and development policy is the other half of the energy question, namely energy demand. In 218 pages of text there are no more than 8 pages on factors likely to influence energy demand. This reflects the institutional blindspot to the one energy research and development area likely to pay off most handsomely in the medium term. It seems likely that with a moderate range of incentives UK energy demand could be con-

strained to increase by less than 30% over the next 25 years (compared with an increase of 60% over the past 25 years). If this potential exists with present energy utilisation technology it is likely that further research and development on energy utilisation technologies could lead to even greater savings. The known savings are cheaper by a factor of between three and ten, in both capital and total cost terms, than the equivalent increases in energy supplies. This indicates that there is considerable scope for developing additional energy-saving technologies before they cost as much as the energy supply technologies. This is recognised in some of the small print in Walter Marshall's discussion document *Energy R & D in the UK* (Department of Energy, Series of Papers on Energy, June 1976), but is ignored in practice. It seems that Kenward has been unduly influenced by the massive volume of literature and finance associated with energy supply technology and has missed perhaps the largest 'potential energy' area in an otherwise useful review. □

Climate and landforms

Robert P. Beckinsale

Geomorphology and Climate. Edited by Edward Derbyshire. Pp. xii+512. (Wiley-Interscience: New York and London, August 1976.) £14.50; \$29.

THROUGHOUT the twentieth century the direct and indirect influence of climate on the shapes of landforms has been generally admitted, and the cult of distinctive landforms in distinctive climates has become a hallowed geographical tradition. There is much in its favour because the characteristic landforms in cold glaciated lands, hot deserts and humid tropical regions seem to differ markedly from each other. So climatic geomorphology grew up as a zonal concept wherein each broad thermal belt tended to develop its own specific complex of dynamic processes. Climate was exalted as the great panjandrum, the universal supplier of solar energy and the creator of kinetic energy for the moisture machine. Climatic geomorphologists seemed to be over-riding the doctrine of James Hutton:

"Our land has two extremities; the tops of the mountains, on the one hand, and the sea shores, on the other:—While there is a sea shore and a higher ground, there is that which is required for the system of the world: Take these away, and the world would remain an aqueous globe, in which the world would perish."

Yet it is obvious enough that before climate can work on rock surfaces, some of the latter must be raised above sealevel; once exposed they will probably consist of differing geological compositions which will withstand the attacks of weathering and erosion in different ways and at different rates. Most landforms must be considered to represent the interactions of their structure, stability relative to base level, the processes at work on them past and present, and the length of time for which those processes persisted. The complex nature of each of these parameters and the multitude of possible combinations of their variables ensure as regards surface shapes—or slopes, or whatever is meant by morphometry—that all forms of hillslope occur in all climatic environments.

The scientific analysis of the shape and spatial distribution of landforms is an enormous task still largely uncompleted yet it forms the basis of early climatic geomorphology. The later or latest trend is to determine

the exact cause and rate of the climatic process, and in turn to determine the relative importance of each major component of climate. At the same time the relative importance of the passive parameter, the rock structure, may also be revealed.

It is in this spirit that *Geomorphology and Climate* presents an analysis of the interactions between climatic processes and the shape of landforms. Written by fifteen well-known authors from Australia, Europe and North America, it can safely be said to be authoritative and certainly is neither dull nor dogmatic. It opens with a broad survey of the problems on the assumption that the central concern of climatic geomorphology lies in the extent to which variations in the elements of climate are reflected in geomorphic processes to produce distinctive suites of landforms. After a discussion of the traditional approaches by way of broad zonal patterns based largely on climate, vegetation and soils, the evidence of surface shape is shown to be inadequate as the sole basis for testing the influence of climate on landforms.

The following six chapters proceed in a logical sequence to discuss climatic interactions involved in rock weathering, mass wasting and the development of soil catenas and slopes. As would be expected of these experienced campaigners, the approach is modern, thorough and objective. For example, we learn that attempts to classify mass-movement types and frequency and their role in landscape development in terms of climatic parameters are doomed to failure; that, except in extreme situations, it is premature to relate climatic-geomorphological systems to soils; and that at medium or regional scales, slope forms cannot usefully be viewed as responses to climatic variables alone.

The next four chapters deal with water in hydrological slope models, with fluvial erosion rates, drainage networks, and, using West Malaysia as a detailed case study, with the role of climate in denudation. In these fields the influence of climate seems to be more securely established. For example, although several of the interactions are poorly understood and much more practical measurement is needed, the present findings and models of hydrological slopes are 'reasonably acceptable' and, moreover, within morpho-climatic zones the values of drainage density do reflect the climate.

Inevitably the discussion then turns, in chapters 12–14, toward lithology, which provides the framework and constraints in which climatic influences bring about the nature and rate of weathering, denudation and erosion.

There seems to be no doubt that geological factors may become dominant on a small scale and tectonic factors on a somewhat wider scale. The relative importance of rock composition is analysed with particular reference to granites, limestone, sandstones, schists and basalt. Just as the use of standard climatic means is being replaced by that of more pertinent extremes, so the use of crude rock types is being refined by the subtleties of microscopic analysis of rock composition and texture.

The concluding chapter gives a nicely rounded account of climatic factors in cirque formation. Not surprisingly, as cirques are often partly inherited from a pre-existing fluvial system and have close relationships to faults, the authors found it difficult to make generalisations on cirque variations in relation to climate.

This excursion to the snowline inadvertently draws the reader's attention to the absence of chapters on glacial, periglacial, and arid geomorphology. But the editor has already explained this omission. In his opinion, large-scale global, zonal or regional groupings, known as climatic geomorphology, reached their acme in 1950–65 and probably cannot profitably be taken much further until their broad assumptions have been fully tested by establishing the precise relationships between landform shapes and climatic parameters. Consequently this text is on geomorphology and climate.

Bear in mind, however, that in landform evolution the present dynamic processes are often not the key to the past, and that, as an American wit said, the landscape has been out of doors a long time. Because of wide swings in climatic zones during the Quaternary and the remarkable survival and reappearance of relic features from the more distant geological past, over large areas the present landforms are partly a product of past processes. But present processes do, however, provide the key to present denudation and therein lies much of the value of this collection of essays. An understanding of geomorphic processes and of their influence on the existing landscape is essential to Earth Sciences in an age when man's disturbance of the natural environment has become excessive. Consequently the advances in knowledge and experimental techniques discussed here are to be welcomed, especially as the clear exposition and frequent diagrams make them readily intelligible. □

Robert Beckinsale is an Emeritus Leverhulme Fellow and Supernumerary Fellow of University College, Oxford, UK.

Climatic change for better or worse

Hans Mörth

The Genesis Strategy: Climate and Global Survival. By Stephen H. Schneider. Pp xxi+419. (Plenum: New York and London, 1976.) \$14.95. *Forecasts, Famines and Freezes: Climate and Man's Future.* By John Gribbin. Pp. 132. (Wildwood House: London, 1976.) £4.95.

AUTHORED by one of the world's leading atmospheric research scientists who has specialised in the study of climate and its socioeconomic implications, Stephen Schneider's *The Genesis Strategy* has all the ingredients of a classic in its field. Nine chapters, ranging from strictly scientific aspects of atmospheric behaviour to the broad sociological spectrum of governmental strategy in the face of possible disaster, provide an immense wealth of food for thought. Written splendidly with the assistance of Lynn E. Mesirow, this book is likely to appeal most to those intellectuals who, despite having worked for years with logical reasoning and cold numbers, have maintained an open mind and heart for the real problems of this world. For the scientist, there is a wealth of useful references to literature on recent research in climatology and other related disciplines. Thirty-eight well selected diagrams provide the illustrations for key issues discussed in the text.

I will concentrate on the scientific atmospheric aspects of Schneider's work. A short account of recent climatic fluctuations leads up to the crucial question whether human activities have contributed to their occurrence. Inadvertent climate modification by man's activities is unquestionably gaining importance while present trends of the world's industrial activities continue. But, have we reached the point where large-scale climatic features can be produced? Although there is a general appreciation among climatologists of the basic problem (and it is a real problem), Schneider's emphasis and timing are likely to be regarded as overdone and premature. Nevertheless, in the spirit of the message conveyed by this book, there is justification for over-anxiety, as some consequences of inadvertent climate modification are irreversible once the point of no return has been passed.

One chapter is devoted to the problem "Climatic History—What if it Repeats?". Excerpts from well-documented accounts of historic climatic events provide a convenient introduction to this topic. The prehistoric 'palaeo'-climatic period, especially the occurrence of ice ages, is also briefly discussed. The lessons to be learned are manifold and important. Essentially, the study of past climates requires an interdisciplinary approach, including archaeology, geology, glaciology, history and palynology, among others.

A review of the theory of climate is presented. Here, the meteorologist reader will feel more on home ground, relatively speaking. Schneider places much emphasis on local changes of albedo on land surfaces due to differential land use, especially grazing of domestic animals. These albedo changes can be detected on photographs taken from Earth Resources Technology Satellites (ERTS). It is my opinion, however, that these are no more likely or unlikely to affect the large-scale circulation of the atmosphere than the condensation cloud trails produced by vast numbers of aircraft. Schneider does not consider the effects of the latter, whereas the bedouins are mentioned in three different contexts as possible culprits behind the Sahel drought disaster. Later in this chapter, it is conceded that climatic cause-and-effect linkages are very difficult to prove because there is still no adequate quantitative theory to explain any of the possible causes responsible for a particular climatic event.

Sixty pages of this volume deal with specific aspects of weather and climate modification. This is probably the most comprehensive presentation of topical aspects in this field available at present. In a world scarred with the effect of man's disastrous attempts to interfere with nature it is most satisfying to follow Schneider's thoughts on the advisability and wisdom of climatic control: "Control the Climatic Controllers, Not the Climate".

The climatic influence on food production, the present state and future needs of food supply for the world's population, and the dilemma which is likely to arise in the near future are portrayed with clarity and conviction in the focal chapters of this book. Following the pattern of climatic extremes which adversely affected crop production of the world's grain belts in recent years, the question of "can something be done?" looms between the lines.

Assuming that Stephen Schneider regards himself basically as an atmospheric scientist, the fundamental question arises whether scientists should pursue their professional activities

regardless or whether they should make an effort to ensure that the application of scientific knowledge to national and international problems is scientifically sound and morally justifiable. In writing this book, Schneider has emphatically affirmed his willingness to share the responsibilities towards the world. No doubt, the outspoken manner of his treatise will raise a number of eyebrows and tread on a number of toes. Perhaps, this is just what is needed in some circles of the profession which have become complacent over solving 'their' problems by finite difference steps—*ad infinitum*.

THE contents of the second book, *Climate, Famine and Freezes*, deal with two aspects: evidence for the notion that climate is changing, and scientific work dealing with this problem.

An outline of the large implications for today's economies of relatively small-scale climatic trends and fluctuations supports the view that climatic research is essential and a matter of urgency. Attention is drawn to the potentially high benefit-cost ratio for research in this field.

An account is given of recent temperature and rainfall trends, some of which have already infringed drastically on human life—for example, Sahel droughts, and Mediterranean region summer rains. Some of the statements and conclusions are fleeting and lacking in precision. The essential features of recent climatic trends, however, are well enough portrayed, and the recent drought (1975–76) in north-western Europe and the British Isles fits well into the picture.

On previous climatic changes, the author describes methods and techniques of obtaining prehistoric weather information indirectly (by proxy) from tree rings, sediment varves and pollen spectrum analysis. Attention is drawn to recent work in Africa linking equatorial rainfall with the extent of glaciation.

Implications of recent variations in the area covered by ice and snow in the Northern Hemisphere on the weather and climate, are discussed. Any hints at the likely causes of these changes must at this stage be regarded as pure speculation.

Gribbin devotes a chapter to the question of solar influences on weather—a most controversial and debated aspect of atmospheric science. Whatever the reader's view on this matter he must concede that the information given makes interesting reading.

Climatic trends of a long-term nature and their derivation from historical and prehistoric evidence are discussed. This work is gaining importance with regard to climatic forecasting as it delineates the boundaries within which the climate varied in the past. As one climatologist

put it: "What happened in the past can happen again". Unfortunately this theme leads Gribbin to speculate on solar-terrestrial weather relationships of a kind for which no scientific proof will be possible in the foreseeable future.

One of the most recently explored geophysical aspects of weather and climate is the Earth's magnetic field. Although this subject may be anathema to those meteorologists who believe that one can well manage without it, there is certainly justification for research, especially as good long-term records exist. At this stage of affairs, one simply cannot afford to reject outright a possible influence on, or association with, climate and its variations.

A better understood, but equally difficult, field of meteorology is the penetration of solar radiation through the atmosphere; or, looking at the other side of the coin, the loss of surface heating through interception of solar radiation by dust, clouds and aerosol in the atmosphere. The author correctly stresses the sensitivity of polar and sub-polar ice and snow cover to the delicate heat balance in high latitudes.

The question whether man's activities are changing the climate is dealt with in its widest terms. The author's treatment reflects the present majority opinion among scientists working in this field: although evidence for small-scale effects already exists (urban heat islands, rainfall modification, and so on), the large-scale atmospheric circulation is still overwhelmingly governed by "natural" events.

An objective and balanced view is taken in the discussion of the prospect for an early and sudden reversal to ice-age conditions. Major theories of global cooling are presented and put into perspective. One passage in the description of the astronomical theory of ice ages—"The most extreme effect by this process reduces the intensity of sunshine reaching the Earth by 30%"—is likely to produce an erroneous impression in the reader. Incidentally, Gribbin is in very good company when tackling this explanation, as Sir John Herschel may also be accused of misleading the readers of his *Outlines of Astronomy* (1875 edition) when he wrote: "... by concentrating half the annual supply into a summer of very short duration and the other half over a long and dreary winter, . . .". When Gribbin writes that the world's climate involves more complex factors than a simple dependence on variations in solar energy produced by changes in the Earth's orbital motion, he really puts the finger on the right spot.

Another important point is brought out in the discussion of the limitations to conventional forecasting techniques. Numerical computerised forecasting

techniques of the kind applied at present to the production of short-term (up to 72 h) forecasts cannot be stretched to cover longer periods while still providing acceptable results. Development of long-term forecasting requires the inputs of different kinds and timescales, including slow-acting feedback mechanisms, such as may be produced by changes in ocean surface temperatures. Present attempts at climatic forecasting are very much in the experimental stage.

Evidence for the association of grain and food production fluctuations with the sunspot cycle is scanty and covers too short a period. Surely a good number of the ups and downs of agriculture around the world are bound to coincide with sunspot maxima and minima. What about the remainder? More relevant and indeed important is the problem of crop failures due to weather extremes in our times when the world's

food reserves are nearly exhausted. Gribbin draws a far-reaching conclusion: that the economic policies of many countries may have to be altered.

In a postscript, the ultra-long aspect of changes in the Sun's radiation due to the Solar System passing through dust lanes in the spiral galaxy are considered. Gribbin's flare for an astronomical view on the problem is appreciated.

This book is a well written popular account of the state of the art of explaining the past and speculating on future climatic changes. It contains the essentials of present knowledge of this subject. Good bed-time reading for the layman and unbiased meteorologist. □

Mathematical models in ecology

John H. Lawton

Theoretical Ecology: Principles and Applications. Edited by R. M. May. Pp. viii+317. (Blackwell Scientific: Oxford, London, Edinburgh and Melbourne, 1976.) Cloth £8.50; paper £4.80.

I ONCE heard Charles Elton say that the trouble with ecology was that it was "fun to do, but not very interesting to read about". This book makes it abundantly clear that ecology is now not only exciting to do, but also makes excellent reading.

The aims of the book are very simple: it seeks to review and draw together a whole series of mathematical models, to show how they can shed light on empirical observations and to examine some of the practical implications. In so doing, it occupies a niche between the numerous large general textbooks of ecology that have appeared recently, and the more technical literature that cascades on the world in the form of journals and specialist monographs. It embraces a range of subjects reflecting the core of current interest in theoretical ecology.

Certain relatively small areas receive scant or no mention (for example, optimal foraging theory, or spatial patterning in vegetation), and the book draws almost entirely on theoretical models that can be handled analytically. Large scale computer simulations

('dirty great' as opposed to 'little dirty') models figure hardly at all. It is also a theoretical edifice built on an inverted pyramid of biomass, with animal examples well in excess of plant examples. These are not criticisms.

The organisation of what the book does cover is conventional, and sensible. It starts with an examination of the dynamics of single species populations by May, and is followed by a review of the evolution of major population characteristics by Southwood. Between them, they illustrate particularly well something of the how and why a population's characteristics are as they are (in the resources allocated to reproduction, longevity, and so on), and how these characteristics influence its dynamics. Interactions between two populations are considered in the next four chapters, which deal first (by May) with some of the general features of predation, competition and, less conventionally, mutualism; and then in more detail with arthropod predator-prey interactions (by Hassell), plant-herbivore systems (by Caughley) and competition and niche theory (by Pianka). One of the more interesting things about ecology is the possibility of advance from a consideration of the dynamics of a single species or pairs of species and ignoring all the rest. It looks like cheating, but it also seems to work, as the interplay between theory and practice developed in these first six chapters clearly illustrates. In reality, perhaps many ecological systems are very loosely connected in terms of the major controlling links between species.

In certain cases, of course, it is misleading or nonsense to confine attention to single species, or pair-wise interactions. Various multi-species problems

are therefore considered in the next three chapters, which deal respectively with patterns in multi-species communities (by May), island biogeography and the design of nature reserves (by Diamond and May), and succession (by Horn).

The remaining four chapters would not normally be classified in the mainstream of theoretical ecology—friends or half-cousins perhaps, but not close family. In fact, they link rather well with the rest of the book, and serve to remind us that the traditional boundaries of the subject are in a state of flux. Wilson provides a brief overview of some of the central problems of sociobiology as he sees them and forces the reader to think about such problems as group selection, the evolution of sex, and adaptive demography. Gould expands the timescale of traditional ecological thought and attempts to bridge the ravine between palaeontology and ecology; and Cohen directs our thoughts inwards to the biological and ecological puzzles presented by our schistosome parasites. Finally Conway shows how ecological ideas can provide important insights into the behaviour of another group of nasty animals—insect pests.

Two criticisms are frequently levelled at multi-author texts: lack of cohesion and a large variance in performance. Neither can fairly be levelled at this book. Each author takes particular pains to draw on, and refer to other parts of the book. To give but two examples. Conway makes very successful use of the concept of the 'r-K' spectrum documented at length by Southwood, and Gould is able to use the species-area relationships that form the backbone of the chapter by Diamond and May, to provide a convincing explanation for one of palaeontology's biggest paradoxes—the Permian crisis of extinction. This interplay of ideas is obvious throughout the book. The papers do vary in quality, of course; all are worth reading, and most are of the highest standard. I found the paper by Caughley the most disappointing, in that it makes the least convincing contact of all between the real world and the models, but I suspect this is as much a fault of the lack of data as anything else.

This book will surely be essential reading for all serious students of the subject (both advanced undergraduates and postgraduates), and a valuable source of authoritative summaries and guide to the literature for teachers and research workers, for several years ahead. Not only will they learn a lot: they ought to enjoy it. I did. □

Room with a view

K. G. Eldridge

The Natural History of Trees. (The World Naturalist Series.) By Herbert L. Edlin. Pp. xvi+269+66 plates. (Weidenfeld and Nicolson: London, September 1976.) £10.

HERBERT EDLIN looks out at trees and forests of the world from the window of a country house not far from London. There is much to be seen and learned nearby, and much more to be remembered from his earlier experiences in other lands.

There are fine precedents for his approach to writing a natural history book: *The Origin of Species* was written from a house with a similar view. Edlin's latest book, however, does not present any grand concept or develop a thesis. It is descriptive, aiming to present factual information which might form the basis of ideas and rational action.

Administrators, politicians, some scientists and engineers, students, and other people who argue about the use of forest land, whether to chop trees down or grow more, often talk in ignorance of the basic biology of trees. This book will be a useful introduction to informed discussion.

Edlin deplores policies of single use of forests and advocates prudent multiple use. He does not like the current single-use ideas of wilderness, conservation, restricting access and allowing little or no management. Nevertheless he agrees that forest conservationists have reason to be active and angry. He shares their outrage at the single-use policy called "cut out and get out" which has exhausted much of the conifer forests of the west coast of North America.

People do not put a high value on their forests while wood and other products are available in unlimited amounts at no cost, like fresh air. The value of these commodities only becomes apparent as they are depleted or obliterated. With forests valued more highly and with a greater understanding of forest biology Edlin expects some of the dilemmas of the use of forest land to be resolved.

As a naturalist he has an obvious pleasure in trees and in understanding the natural processes of their life. His descriptive writing is attractive and clear, touching on every aspect of the

biology of trees both as individuals and in communities. Following the familiar pattern of the older textbooks of forest botany he describes the anatomy and development of seeds and seedlings, wood and trees, the ascent of sap, and the annual cycles of leaves and flowers. The descriptions are brief and accurate but the illustrations are inadequate. Good illustrations are essential to supplement the description of the cambium and how it makes wood, or of the guard cells of stomata and the way they let water vapour and air in and out of leaves.

Throughout the book Edlin shows a preference for writing of "purpose" rather than of "function", of "winged seeds designed for wind dispersal", as though the tree had decided and acted on what was best for itself. Such a teleological explanation seems simple, as it avoids the issue of evolution. Unfortunately it denies the reader the great satisfaction, which Julian Huxley and other splendid English writers on natural history gave us, of recognising adaptations as being the result of natural selection.

The descriptions of trees in communities in relation to soil, light and climate show how one kind of tree replaces another and the dependence of trees on their environment. The crowns of large trees in a forest are exposed to the macroclimate of the district, while the floor of the forest has a calmer, darker, more humid environment with less fluctuation in temperature. The author shows a special interest in the effects of wind on trees.

His outlines on forest soils and soil erosion give little hint of the vast amount of information on those subjects. In fact he could have mentioned several textbooks for every page of the whole book, but there are no references to any other publications.

With the scientific forester's approach of "wise management for sustained yield" he describes the many sorts of forests throughout the world and the ways they are used. In his account of the characteristics of broad-leaved and conifer forests of the Northern Hemisphere his explanations of the distribution of species are too brief to be satisfactory. One might agree at first that conifers predominate towards the Arctic because it is an advantage for a tree to be evergreen and ready to grow immediately the temperature is warmer than 6 °C. Edlin does not, however, discuss the rapid growth of the deciduous birch which is always present with the pine and spruce at the far northern timberline.

There is a similar lack of space to do justice to the complex ecology of the open savanna forests of tropical countries. Small trees grow in a grass-

land sustained by man-made fires, but when eucalypts are planted they soon outstrip the native trees. A recent explanation, which the author does not mention, is that the roots of foreign trees can penetrate a hard layer deep in the soil, which is impervious to the roots of native trees, and obtain water from greater depths in the dry season.

The material in the book is more about the trees and forests of southern England than elsewhere. Consequently its greatest appeal is likely to be to those readers close to the writer's familiar home ground who also would like a glance at living forests of the rest of the world.

Some of the most attractive parts of the book are those in which the writer gives an account from his personal experience of a forester's daily life in England, of a Malaysian rubber plantation and of rainforests. Edlin gives a lively description of the complex, diverse and changing tropical rainforest and notes with regret that the modern rainforest "is more likely to be raped than virgin".

Being an experienced writer in his field of popular forest science, Edlin

is concerned to be correct in his factual information. The few minor inaccuracies I noticed probably resulted from the brevity needed to fit such a large number of topics into 269 pages. For example, it is not correct to say the natural range of *Eucalyptus saligna* is in a Mediterranean climate. It is in an area of predominantly summer rainfall grading into a winter rainfall, Mediterranean climate at the southern end. Also, it is not correct to suggest that sulphite pulps are the main raw material for small paper bags, although they are sometimes used.

It was a curious decision in an otherwise well-produced reference book to have no suggestions for further reading to encourage the interest aroused in students. There should have been room for a bibliography and also a glossary. Nevertheless Edlin's book is readable and informative and will be a useful general reference for newcomers to the study of trees. □

Broad canvas for cytoplasmic genetics

R. A. E. Tilney-Bassett

Cytoplasmic Genetics and Evolution. By Paul Grun. Pp. xi+435. (Columbia University: New York, July 1976.) \$31.25.

THE publication of a book in the field of extranuclear inheritance is a rare and welcome event. Paul Grun begins by establishing the physical properties of mitochondria and plastids, and their potential for genetic variation through mutation, segregation and recombination. A few of the more important mitochondrial and plastid enzymes are each briefly described, as if the author wished to emphasise that he had not completely neglected the biosynthetic capabilities. But, in my view, this was insufficient to serve much purpose and a greater attention towards clarifying the often quite complicated genetical accounts would have been more valuable. Nevertheless, I was impressed by the way in which the reader is briefly and carefully guided through the experimental procedures, and by the way the evidence is sifted and both sides of controversial issues discussed.

A large section on symbiotes and inherited diseases extends cytoplasmic inheritance into consideration of the relationships between bacteria and their insect hosts, spirochetes in *Drosophila*, killer paramecia and killer yeasts, and the problem of cancers in vertebrate animals. Non-cancerous diseases are also discussed using the example of scrapie in sheep and Leber's optic neuritis in man to illustrate the importance of understanding the interactions between nuclear genes and transmissible factors. Yet, surprisingly, Grun fails to drive home the message that probably several other diseases might be better understood if regarded in this light. Having opened the door to discuss symbiotes, I was disappointed to find no mention of those remarkable chloroplasts that can exist endosymbiotically in the cells of some molluscs and other invertebrates.

The final of the four parts catalogues many examples illustrating the importance of the plasmon as the causative factor in determining some of the stranger facts of cytoplasmic genetics. Particular attention is given to the interaction between nuclear genes and plasmon factors, as for example in cytoplasmic male sterility, and to the evidence for genetic variability and evolutionary change within the plasmon. The chapters of this part add up to an extensive and thorough review reflecting the author's close familiarity with this little understood subject—a genetic backwater that needs this kind of publicity.

To bring together into one book such a wide range of genetic phenomena is a Herculean feat—over one thousand references are quoted. But Paul Grun is not content with pure description; he has attempted a modern synthesis in which he relates cytoplasmic phenomena to varying states of an overall evolutionary process. Whether we look at a parasite starting to invade a new host, or a long established organelle like a mitochondrion, there is a continuing process of genetic and physiological adjustment by which host and invader work out a strategy to their mutual advantage. Gradually, the successful parasite may become the universal symbiont and essential organelle. Initially the host may not be able to resist invasion, yet slowly and inexorably, through mutation and selection, the host nucleus gains control. At this stage any major disturbance to the harmonious relationship between the two is strongly selected against, and so the interaction between nucleus and cytoplasm becomes a restrictive force on evolutionary divergence. So close and so delicate is the interaction, that we find many examples of geographical races or neighbouring species, in both plants and animals, that fail to form healthy fertile hybrids because the hybrid nucleus is incompatible with the maternally inherited cytoplasm. In short, the cytoplasm has become an important force in evolution.

The evolution of a mechanism to limit the transmission of cytoplasmic factors to the female line is seen as a strategy by which the host effectively stops the recombination of cytoplasmic genes and thus gains mastery over their behaviour. Once sufficient control is acquired, the host nucleus may even take over some organelle genes as seems to have happened in the splitting of the cistrons for certain plastid enzymes between nuclear and plastid DNA, and in the reduction in coding capacity of vertebrate mitochondria compared with that of yeast or higher plants.

Although some areas are covered too thinly, the author's aim to paint a broad canvas covering the more important aspects of cytoplasmic genetics is generally successful. Above all, the illustrated book is written in an easy style, and it makes such fascinating and enjoyable reading that it should have a wide appeal to degree students in the biological sciences as well as to research workers. It is to be hoped that the high cost does not prove too great a discouragement for a book that deserves to be widely read. □

Modern microbiology

Sydney Selwyn

The Development of Microbiology. By Patrick Collard. Pp. 212+xx photos. (Cambridge University: Cambridge, London and New York, November 1976.) £6.50.

THERE is probably no field of science or medicine which has a more fascinating and exciting history than microbiology. Paul de Kruif's classic, if over-romanticised, epic *The Microbe Hunters* has undoubtedly stimulated many young people to enter the medical and related professions during the 50 years since it was first published. The same source provided initial inspiration for the recent British television (BBC2) series *Microbes and Men*. The enthusiastic reception which greeted these dramatised sequences showed that the history of medical microbiology maintains a very wide appeal.

Paradoxically, however, this enthralling subject has received relatively little serious historical study. William Bulloch's *History of Bacteriology* stands alone as a detailed but idiosyncratic work. First published in 1938 it is now, sadly, unavailable. A briefer account by W. W. Ford, written in 1939, was followed more recently by W. D. Foster's general history. This contains a good survey of important French and German achievements of the nineteenth century but it neglects the earlier (and most recent) periods, and much of the less familiar British work. A very welcome event, therefore, is the publication of a new historical survey by Professor Collard of the Manchester Medical School. It arose from lectures to postgraduate students of medical microbiology and is admirably suited for such an audience. The cognoscenti, too, will find many delights but these will inevitably be tempered by disappointments especially in relation to the 'archeological' period before Pasteur.

The book is divided in a very practical way into thirteen main chapters which consider in turn the development of such aspects as microscopy, microbial cultivation, chemotherapy, genetics and serology. The author has wisely resisted the temptation to deal chronologically with the entire subject *en masse*. At the outset he delineates four eras through which microbiology has passed: speculation, from 5000 BC

to 1675; observation, from 1675 to the mid-nineteenth century; cultivation, to the beginning of the twentieth century; and the era of physiological study, persisting to the present day.

Although this view has the merit of simplicity, it presents a static picture of a dynamic subject. In particular, it ignores the fact that the volume and quantity of speculative writing actually continued to rise steadily after 1675. The later landmarks include Benjamin Marten's book on consumption of 1720 and Richard Bradley's treatise on the plague of the following year, but hundreds of others could be cited, culminating, during the mid-nineteenth century, in the writings of Jacob Henle on infection in general, William Budd on typhoid and John Snow on cholera.

Perhaps surprisingly, the greater part of this work was British—as was a remarkable amount of more practical investigation. Microscopy begins logically with the elegant treatises on lenses by Roger Bacon and other Oxford philosophers of the thirteenth century, proceeding through the work of such forgotten figures as Leonard Digges, the elder, in the mid-sixteenth century.

The first practical microbiologist, however, was probably Thomas Moffett. This English physician, who is likely to have been the father of the celebrated "little Miss Muffet", not only described the infective cycle of silkworm disease, but also in 1589 provided a practical basis for a germ theory of disease with his study of the biology, pathology and treatment of scabies. Although Moffett is the undoubted founder of parasitology—and conceptually, of medical microbiology—he is totally neglected by the historians of these subjects. So also is one of the greatest theoreticians of all time, Francis Bacon, whose writings contain the roots of all that was to follow in microbiology. His assertion that an understanding of the processes underlying fermentation and putrefaction would be the key to the mysteries of disease and other "operations of nature" forms the basis for the later researches of Boyle, Willis, Pringle and their successors. Similarly, his perceptive remarks on the potential value of the new microscope lead directly to the work of that remarkable group of pioneer microscopists of the mid-seventeenth century—Mundy, Charleton, Power, Grew and Hooke. Only the latter has received any attention by historians of microbiology, and Professor Collard gives him merely passing mention.

Van Leeuwenhoek receives a more adequate amount of space, but some misconceptions need to be dispelled. He did not arise *deus ex machina* but

his single-lens microscopes are perfect replicas of the type fully described ten years earlier by Robert Hooke, who also provided the idea of modified dark-ground illumination which probably determined van Leeuwenhoek's later successes. The Dutch draper was, moreover, incapable of producing the drawings contained in his famous letters to the Royal Society. Clifford Dobell, his reverential biographer, describes the mediocre quality of the work done for van Leeuwenhoek by his draughtsmen. So much so, that Professor Collard identifies "streptococci" from a sketch intended to portray, with a series of dots, the track of a mobile bacillus.

There are few such problems of interpretation in the modern period, although the story of Fleming's rediscovery of penicillin needs overhauling following Ronald Hare's revelations. Also Domagk's prontosil red was virtually inactive *in vitro* and was relatively ineffective against pneumococci *in vivo*. These and other minor errors should not be allowed to dissipate our genuine gratitude to the author. He has written the best available account of the development of modern microbiology. □

Imaginative processes come of age

P. W. Hawkes

Optical Information Processing. Edited by Yu. E. Nesterikhin, G. W. Stroke and W. E. Kock. Pp. xiv+401. (Plenum: New York and London, 1976.) \$39. *Digital Picture Processing.* By A. Rosenfeld and A. C. Kak. Pp. xii+457. (Academic: New York and London, 1976.) \$28.50. *Picture Processing and Digital Filtering.* Edited by T. S. Huang. Pp. xiii+289. (Springer: Berlin and New York, 1975.) DM79.80; \$34.40. *Principles of Optics.* By M. Born and E. Wolf. Pp. xxviii+808. (Pergamon: Oxford and New York, 1975.) £10.50; \$22.50.

TEN years ago, digital image processing hardly existed and optical processing was in its infancy. Microscopists, radiographers, archaeologists studying aerial photographs and a host of other users of images of some kind were well aware of the shortcomings of their interpretative techniques and they at best overcame or at worst disguised them by slowly accumulated experience. Nevertheless, optical processing cannot truly be described as a new subject, for it consists in combining a thorough knowledge of the optics of the image-forming process with some ingenious optical designing intended to avoid the most troublesome of the inherent limitations, probably at the expense of worsening less harmful ones: apodisation is an obvious example. The sudden interest in optical processing in the 1960s was stimulated by the arrival of the laser, which permitted essentially coherent processing, although complementary incoherent techniques have also emerged or been reconsidered in the general revival of studies in this domain.

Digital image processing is, on the other hand, a genuinely new subject, which could not exist before fast computers with very large memories became widely disseminated. To a computer, an image is no more than a two-dimensional array, usually as large as possible, of real or complex quantities; and the challenge of computer processing is a complex one: the discrete array must represent the recorded image, however degraded this may have been in the image-forming process, as faithfully as possible. This means studying the properties of the photographic medium and the optical properties of

the microdensitometer (unless the image is transmitted sequentially, as in a scanning device for example). Optimum strategies must be devised for rendering the discrete image better, in some carefully defined sense, or more informative, in the sense that the eye can recognise detail of interest more easily or that a quantitative measure is obtained of some property about which only qualitative information had been available. Finally, the processed image must be made visible preferably in a way that makes obvious its superiority over the original.

A number of books and review articles on coherent optical processing, many devoted mainly to holography, have appeared over the past few years and the volume by Nesterikhin *et al.*, which contains the seventeen papers delivered at a US-USSR joint seminar in 1975, is an uneven addition to this body of literature. In particular, some authors have been at pains to situate their work relative to earlier contributions, whereas others merely give a bald account of their own research; since there seems to have been no length limit—one chapter, an excellent one on the information content of diffraction patterns by B. J. Thompson, is 34 typed pages long—this approach is difficult to forgive. There are chapters on both the technology and the theory of optical processing, ranging from one on materials and devices by Casasent and another on holographic memories by Vander Lugt to a survey of speckle by Goodman and a discussion of holographic memory devices for specific integral transforms by Gibin and Tverdokhle. It is useful to see the lines which Russian scientists are following, as the only other sources of Eastern material, original articles apart, are the occasional Sborniki that have been compiled. Finally, a word about the editing: the book has been offset directly from typewritten texts submitted by the authors. For the price, the editors could surely have had the text retyped uniformly which would not only have produced a less scrappy-looking text but also have permitted genuine editing: the removal of such bizarre transliterations as "the Fuco-Hilbert transform" for example and the provision of some assistance to authors whose English was shaky.

In the field of digital processing, a torrent of books, many of a very high standard, has recently flooded on to the market, supplementing and replacing the excellent early texts by Andrews and Rosenfeld (by 'early' in this context we mean 1970 and 1969, respectively); indeed, the volume by Rosenfeld and Kak supercedes Rosenfeld's earlier book, and a new and expanded edition of Andrews' text is promised for the new year. The volume

by Rosenfeld and Kak and that edited by Huang contain essentially similar material, concerned with the mathematical representation of images in discrete form, compression of the information, often highly redundant, contained in them, the enhancement of contrast and the restoration of degraded pictures and some pattern recognition techniques; the latter are, however, much more fully described in other recent books not noticed here.

Picture Processing and Digital Filtering contains six contributions: a clear survey by Huang, putting the detailed chapters in perspective; an extremely good account by Andrews of most of the two-dimensional transforms in algebraic terms; separate chapters on recursive and non-recursive filters by Read, Shanks and Treitel, and by Fiasconaro, respectively; by far the best available account of mathematical techniques for image enhancement and restoration by Frieden; and a good account of the effect of noise, firmly related to the type of equipment used at present in image processing, by Billingsley. All these chapters are extremely clearly written and above all, given the novel status of the subject, they are written so that the techniques can be used and developed for a wide range of possible applications. The only disappointing contribution is that on recursive filtering, as yet a rather shadowy aspect of image processing, in which the authors never really explain what their techniques are for. But we should probably be grateful for any extended essay on this topic, whatever its shortcomings. The chapters by Andrews and Frieden are masterly and would alone make the book highly desirable.

The book by Rosenfeld and Kak is also very good indeed; although a direct competitor, in the sense that it has a great deal of material in common with Huang's volume, the tone and approach are subtly different—due no doubt to Rosenfeld's preoccupation with pattern recognition and picture descriptors during the past few years. The homogeneity of the writing is pleasant after the inevitable unevenness of the multi-author volume, and Rosenfeld and Kak have devoted a great deal of space and effort to ensuring that the reader grasps the purpose of the many techniques described. Furthermore, whereas Huang's book has the merit that a great many techniques are described by their originators, Rosenfeld's has the complementary merit of comparing and contrasting the same techniques from another viewpoint. In conclusion, most workers in this field will want to have access at least to both of these volumes; newcomers are probably better served by Rosenfeld and Kak's *Digital Picture Processing*.

Finally, we turn to *Principles of Optics*; it is always a pleasure to praise this book, now in its fifth edition. Most of the earlier 'editions' were scarcely more than reprints, as was made clear in the prefaces. But in the fifth edition, much of the material on the optical properties of metals has been rewritten, where the original text was misleading. Although sympathising entirely with Professor Wolf's reluctance to tamper with the text piecemeal in an attempt to bring it all up to date, it would be particularly pleasing if he consented to incorporate into the sixth edition the new material recently published by his own group in the field of partial coherence and the radiometric quantities. Even so, it remains a near-definitive account of classical optics at a very reasonable price. It is included in this group of books on image processing since a thorough grasp of the chapters on image formation at least is indispensable for anyone seriously embarking on digital or optical processing.

How far has image processing got

in practice? In some respects, the mathematics has outstripped the practical applications with the result that the same test images tend to recur repeatedly after undergoing a wide variety of treatments. Nevertheless, the volumes on digital methods may leave the misleading impression that theory and practice are at present far apart, for there is little mention of specific applications: X-ray tomography, for example, or three-dimensional reconstruction of electron micrographs. Despite this, the possibilities are very exciting: solution of the phase problem; extrapolation beyond the classical limit of resolution; the acceleration of picture processing using fast transforms other than the FFT; and many others. The second decade will undoubtedly witness as many innovations as the first, no less unpredictable. □

Proprioception

J. W. S. Pringle

Structure and Function of Proprioceptors in the Invertebrates. Edited by P. J. Mill. Pp. xviii+686. (Chapman and Hall: London; Distributed in USA by Halsted Press; August 1976.) £19.50.

A BIOLOGIST considering whether to read (or purchase) a volume with multiple authorship does well to consider not only the field covered but also the standing of the contributors. The editor's tasks is like that of a building contractor: he cannot construct well without good materials. Of this book it can be said at the start that the authors are well chosen. They come from Australia, France, Germany and the USA as well as from the UK, and have all developed their insight into the subject by original contributions to it.

In 1938, I published what may have been the first paper on Proprioception in Arthropods. Now, 38 years later, 419 out of the volume's 686 pages deal exclusively with this Phylum, and as much is known about them as about vertebrate animals. The diversity of form and function is much greater. A definitive textbook on vertebrate proprioceptors has been written by one man; for invertebrates the task requires a contributory volume and an editor like this one, prepared to identify the most qualified contributors and to perform such integration as is possible.

The chosen definition of 'proprioceptors' is not Sherrington's—his task was easier because he was considering only the vertebrates; this volume covers all "sense organs capable of registering continuously deformation and stresses in the body due to the animal's own movement or to its weight or to other external mechanical forces". So defined, the vertebrate semicircular canals, otoliths and lateral line would be proprioceptors, which may seem absurd. But such a wide definition is indeed necessary for invertebrates, and if this volume is nearly a textbook of invertebrate mechanoreception it is no less valuable as that.

Laverack's Chapter 1 is largely a structural review and well illustrates the diversity. In Chapter 2, Fields, in a review of all aspects of the physiology of the crustacean muscle receptor organ, includes a clear statement of the evidence for a causal relationship between the electrogenic sodium pump and adaptation of impulse frequency, the latest demonstration of the value of this preparation for basic sensory physiology. Our knowledge of the mode of action and behavioural utilisation of this organ is at least as complete as for the vertebrate muscle spindle. Bush follows this with an account of another preparation important to general physiology—the only sense organ known to operate without impulses.

In Chapter 4, Finlayson gives us a comprehensive review of the multiterminal neurone system of arthropods, the importance of which has only recently been fully appreciated. It seems to be responsible for the overall co-

ordination of movement necessary in a primitively soft-bodied multisegmental animal and to provide the main feedbacks by which the intrinsic motor patterns are adjusted to a variable environment. But neither in locomotion nor in the specialised mouthpart and gut receptors (chapter 5 by Wales) is it possible yet to decide whether these multiterminal type II receptors and the chordotonal type I receptors (chapter 6 by Mill) serve a distinct or a complementary function in proprioception.

At the base of the decapod leg are two peculiar groups of internal chordotonal organs which neither cross a limb joint nor are attached to a muscle or apodeme. In chapter 7, Clarac considers the probable role of these organs in the autotomy reflex. The arthropod section of the volume ends with a long chapter by Wright on limb and wing receptors in insects, chelicerates and myriapods, a detailed description by Moulins of the ultrastructure of chordotonal organs and a valuable chapter by Macmillan on apodeme tension receptors. The diagram which this last author gives comparing vertebrate and arthropod proprioceptive systems will no doubt be much used by lecturers, but ought to be viewed with caution in the present state of our knowledge.

As Dorsett points out at the beginning of chapter 11, proprioception in many soft-bodied invertebrates is not the well-differentiated system found in vertebrates and arthropods possessing a rigid skeleton. Most of the locomotor activity of these animals is stereotyped and is pre-programmed in the central nervous system. Orientation to gravity by means of statocysts is, however, widespread and is included under the definition used for the volume; but proprioceptors *sensu stricto* have only been established in a few cases. Spatial equilibrium in arthropods (chapter 12 by Sandeman) needs separate treatment since the necessary information may be obtained, without a special sense organ, by monitoring the relative position of the parts of the body under linear and angular accelerations. Molluscs (chapter 13 by Budelmann) usually have statocysts.

The final chapters of the volume deal with the processing of proprioceptive information. Wells considers its role in learning; Mill and Price give the necessary theory of feedbacks; and Wiersman writes generally on various relevant topics. The editor's final brief contribution picks up some loose ends and highlights residual problems.

Altogether a most useful book, well produced and not unduly expensive. □

American response to Darwin

David L. Hull

Darwin in America: The Intellectual Response, 1865-1912. By Cynthia Eagle Russett. Pp. ix+228. (Freeman: San Francisco and Reading, May 1976.) Cloth £6.30; paper £3.20.

RUSSETT'S well-balanced account of the intellectual response to Darwinism in America further enhances the richly illustrated picture which we already have of the Darwinian revolution. As Russett would be the first to agree, her book could have been entitled just as readily *Spencer in America* because the authors which Russett treats were as likely to have their minds blown to bits by reading Spencer's *First Principles* (1862) as by Darwin's *Origin of Species* (1859). The genuinely scientific character of Darwin's theory legiti-

mised Spencer's Cosmic Philosophy, but the actual content of Darwin's theory had as little impact on its converts as on its opponents.

Russett deals exhaustively with all aspects of 'Darwinism' in America—scientific, philosophical, religious, social, historiographic, economic and literary. In spite of the opposition of the most powerful scientist in the United States, Louis Agassiz, and perversely to some extent because of it, evolution was almost universally accepted by American biologists within a decade after publication of the *Origin*, but the 'evolutionism' which became so popular tended to be Lamarckian and teleological—partly for scientific reasons, partly theological. Theologians were not alone in viewing the death of teleology as the death of God. Yet in slaying Paley, Darwin slew a corpse. Darwin merely shocked nineteenth-century intellectuals into realising how vacuous teleology had become. The Metaphysical Club at Cambridge was the focus of evolutionism among American philosophers. As might be expected, John Fiske, the most enthusiastic evolutionist, was a Spencerian. More serious philosophers such as William James, John Dewey, Josiah Royce, and Chauncey Wright, however, viewed Spencer as so much rubbish which had to be cleared from their path before proceeding on their way. Spencer was the "philosopher whom those who have no other philosopher appreciate" (p17).

The most interesting sections in Russett's book are those in which she deals with Social Darwinism and its effects on such novelists as Jack London, Frank Norris and Theodore Dreiser. Rugged individualism, socialism, aid to the poor, free will and determinism, nature-nurture, the relative superiority of the races, group selection and altruism—it is all here but presented more bluntly and at a safer distance than it is in the current brouhaha over sociobiology. Darwin also legitimised the 'historical method', which for Dewey was the discovery of the particular sequence of conditions which brought about a particular natural phenomenon, for Henry Adams the search for the one great law of history. Adams found his great law in a combination of thermodynamics and the law of inverse squares. Not only was the universe running down, it was doing so logarithmically. The religious phase of human history had lasted 90,000 yr, the mechanical phase would last 300 yr, the electrical 17.5 yr, and the ethereal phase but 4 yr.

Russett's prevailing concern is the interconnections between intellectual disciplines. For example, if Darwin and Wallace actually borrowed the notion

Charles Darwin

of natural selection from Malthus's *Essay on Population* (1798), then the alacrity with which economists like Thorstein Veblen read the basic principles of evolutionary theory back into human affairs was understandable. A quick glance at Malthus's *Essay*, however, brings the argument full circle because in it Malthus justifies his views about human population by reference to biological species in a state of nature. As complex as the interconnections between intellectual disciplines may be, Russett believes that the content of scientific theories can colour the general intellectual climate and *vice versa*. Her final chapter concerns the blow which Maxwell's equations, quantum theory and relativity theory dealt to the absolute, certain, deterministic, mechanistic worldview initiated by Newton.

The book is illustrated with the usual portraits as well as with extremely well-chosen cartoons and paintings. Some of these illustrations convey messages much more powerfully than any printed word could hope to do; for example, the contrast between 'Nature red in tooth and claw' and the cloying romanticism of Albert Bierstadt's painting of the Rocky Mountains. My only criticism is that Russett completely ignores the really excellent scholarship which has been produced during the past dozen years or so on Darwin and Darwinism. If she has read any of the more recent work, she does not mention it. □

review article

Products of the major histocompatibility complex and their relationship to the immune response

Alan Munro & Susan Bright*

The genes of the major histocompatibility complex were first known for the part they played in transplant rejection. Recently, however, it has become clear that the products of that region have an important part to play in the control of the immune response, through their effects both on cooperative and on aggressive interactions between cells. It is now possible to guess at the mechanisms which may underly the association of some major histocompatibility antigens with disease.

IN mammals there seems to be a single genetic region which has a major influence on graft rejection and is known as the major histocompatibility complex (MHC). In recent years there has been increasing interest in the products of this genetic region because of their importance not only in transplantation but in many other aspects of immunology¹⁻³.

The MHC is divided into different regions mainly on the basis of genetic recombinants⁴. The probable arrangement of these regions in mouse and man are shown in Fig. 1. In this review we want to discuss the properties of the MHC as a whole, in particular its unusual genetic properties and the association of certain alleles in the MHC with diseases in man. In order to do this it is essential first to discuss the properties of the genes which lie in the different regions of the MHC, in terms of their genetic properties and in terms of the molecular nature and suggested functions of their products. In this connection it is helpful to compare and contrast the properties of corresponding genes found in mouse and man. We shall then return to the problem of disease association with HLA in man and finally discuss the possible reasons for the unusual genetic properties of the region as a whole.

It is important to have some feel for the size of the MHC and hence a crude estimation of the number of possible genes involved. The MHC covers a length of DNA equivalent to 0.5 recombination units in the mouse¹ and greater than 1.0 in man^{5,6}. The low frequency of recombinants between the different loci in the MHC means that in most cases offspring inherit from each parent all the alleles found on one of the parental chromosomes. Such a set of alleles is known as a haplotype. It is not known how much of the DNA in the MHC codes for protein. The amount of DNA in a piece of chromosome of this size could, however, code for as many as 2×10^3 polypeptide chains⁷. It is important to remember that each region probably contains several genes. When more than one property is assigned to the products of a particular region then it does not necessarily follow that these properties belong to the same gene product. In time each region may be further divided as new recombinants are identified.

The classical histocompatibility antigens (CHAGS)

Historically the first products of the MHC to be characterised were those from the K and D regions in the mouse and the HLA-A and -B loci in man^{1,4}. The products from these regions have many biochemical and functional properties in common and seem to form a group of related molecules, which we shall call CHAGS.

The CHAGS can be detected by using antisera induced by the introduction of histoincompatible cells into recipients. In both species the antigens detected by such antisera are found on all tissues except possibly early embryonic tissue and mature human red blood cells. Individual cells

*Address: Immunology Division, Department of Pathology, University of Cambridge, Tennis Court Road, Cambridge, UK.

from a heterozygous animal express the alleles from both chromosomes while individual sperm seem to carry the CHAGS and other MHC gene products coded for by a single chromosome^{9,10}.

Using different antisera people quickly realised that there were many alleles at each locus. In the mouse each allele of the K and D locus is described by a series of numbers representing individual determinants which fall into two categories; a private specificity which is generally unique to that allele and a set of public specificities which occur in more than one allele. Both types of determinants are on the same polypeptide chain¹¹⁻¹³, although there may be possible exceptions to this rule^{14,15}.

In humans the alleles are typed by using specially selected antisera which probably recognise the equivalent of only the private specificities in the mouse. Consequently each allele is described by one number, for example, HLA-A1, HLA-B5. There is increasing evidence for the existence of public specificities in man which may account for some of the anomalous patterns of reaction found with many anti-HLA antisera^{16,17}, for example 4a and 4b. It is not known if the present typing methods for HLA-A and HLA-B private specificities are adequate for transplant and disease association studies or whether typing for public specificities should be included. This is particularly important as private specificities in mouse and man are not always associated with the same public specificities respectively^{18,19}. It is worth noting that some human specificities of a public type are found in other species²⁰.

By using antisera to the CHAGS to monitor the purification, it has been possible to isolate membrane proteins carrying the corresponding antigenic specificities²¹. In both human and mouse these are glycoproteins of molecular weight ~ 45,000. The allelic forms differ in the amino acid sequence and it seems that the carbohydrates are not responsible for the allelic variants^{21,22}. Amino acid sequence data of the N-terminal ends²³⁻²⁶ have confirmed the structural homology of the K and D region CHAGS previously suggested by shared public specificities²⁷. There is also marked sequence homology between HLA-A and HLA-B N terminal fragments^{28,29}, although as yet the serological evidence for such a homology is weak^{30,31}.

There is structural homology not only between the CHAGS from one species but also between the N-terminal fragments of the CHAGS from different species. This homology lends weight to the suggestion that one is working with homologous systems; but the interspecies homology is less marked than that homology within species, and this raises interesting evolutionary questions. It would seem that speciation preceded duplication to form multiple loci. Ways in which this may have been achieved have been discussed at length elsewhere³².

The human and mouse CHAGS have other features in common. Both are found on membranes non-covalently associated with β_2 microglobulins³³⁻³⁶, remarkable proteins of molecular weight 12,000, which have 30% homology with an immunoglobulin domain^{37,38}. In both animals it seems that the carboxy-terminal end of the CHAGS is involved in attaching the molecules to membranes. A carboxy-terminal fragment of about molecular weight 8,000 is lost if proteolytic enzymes are used to solubilise the molecules from the membrane. The previously isolated polymeric forms of purified human CHAGS are now thought to be artefacts caused by the extraction procedures^{39,40}. Further it has been shown that the allelic products of each locus move independently on lymphocyte membranes^{41,42}. Consequently the molecules only interact with each other very weakly if at all on the surface of cells.

The independent movement of certain determinants on human lymphocytes supports the suggestion that there is a third locus in man, HLA-C, the products of which are

like HLA-A and HLA-B in their tissue distribution and association with β_2 -microglobulin^{35,43}. The relationship between HLA-C and the other two loci (HLA-A and HLA-B) is not yet known, particularly as HLA-C seems to be weakly immunogenic compared to HLA-A and B⁴⁴. The association of the CHAGS with β_2 -microglobulin has led to much premature speculation on the possible evolutionary relationship between CHAGS and immunoglobulin. The structural homology between β_2 -microglobulin and immunoglobulin is such that it is reasonable to assume that β_2 -microglobulin has the same overall three-dimensional structure as a variable region or constant region domain⁴⁵. Immunoglobulin domains readily interact to form dimers, and it has been suggested that the binding of β_2 -microglobulin to the CHAGS occurs by way of a similar mechanism. If this is so there should be a region with homology to an immunoglobulin domain in the sequence of the CHAGS. So far there is no evidence for this though the sequence data are still very limited.

Genetic properties of the CHAGS

We want now to discuss the exceptional genetic properties of the CHAG alleles, which set this system apart from most other known allelic systems. Within a population certain pairs of alleles, one from the A and one from the B locus, occur as haplotypes with a frequency which is greater than or less than that expected if the alleles were randomly associated in the population. This is known as linkage disequilibrium. For example, the haplotypes A1, B8 and A3, B7 are more common in the Caucasian population than would be expected from the frequencies of the individual alleles. Linkage disequilibrium can occur when there has been insufficient time for equilibrium to be established in the population concerned. It is generally thought that this is not the case for the CHAGS in most human populations⁴⁶. Alternatively, linkage disequilibrium can be caused by selective pressures operating in the population to hold certain pairs of alleles on the same chromosome. In different populations the HLA alleles occur with different frequencies and different haplotypes can be found in linkage disequilibrium in different races⁴⁷, which suggests that the selective pressure to establish linkage disequilibrium may be different in each race. Further these pressures need not operate on the CHAGS themselves but on genes on either side of them.

Another unusual feature is that most of the twenty or so alleles at the A and B loci have similar frequencies to each other in the Caucasian population. Selective pressures are required to account for this balanced and extensive polymorphism, for example through favouring heterozygosity^{7,48}. If selection operates through resistance to diseases then such pressures may no longer apply to populations treated by modern medical techniques. In Caucasian families now, segregation of HLA-A and HLA-B obeys the Hardy-Weinberg equilibrium^{49,50}, possibly reflecting the absence of selective pressures in western societies. It is interesting that in at least one population (Tuaregs) there is evidence for heterozygote advantage⁵¹. Because of linkage disequilibrium in the MHC the selective pressures to establish balanced polymorphism of the CHAGS may operate on linked genes, for example, the immune response genes (see later).

In this connection it has been suggested that heterozygosity of H-2 in wild mice may be promoted by the linked *T/t* complex⁵², which is said to control surface structures important in development⁵³. There are lethal recessive alleles (*t*) of several loci in this complex. Two unusual properties of these *t* alleles could lead to extensive heterozygosity at H-2. First, male mice carrying *t* alleles transmit the mutant form to their offspring with an exceptionally

high frequency. Second, many of the *t* mutants suppress recombination over a length of chromosome extending to the H-2 complex. This provides a mechanism by which H-2 heterozygotes are favoured as *t* mutants are lethal in the homozygous state. The *t* mutants are common in wild mice and can be found in as many as 40% of certain populations¹.

There is no evidence that a similar *T/t* complex exists in man, in fact there is evidence to the contrary. The properties of the *t* alleles are such that one would expect to see diversion from Mendelian segregation of the MHC. This has not been observed, at least in Caucasians. It thus seems likely that if the *T/t* complex does exist in the human then it does not bear the same relationship to the MHC as in the mouse. Alternatively the human *T/t* complex may not have the same unusual properties as the mouse complex.

Cytotoxic T lymphocytes and the CHAGS

Although in the past various biological functions have been suggested for the CHAGS^{7,48,52}, there has been little evidence to support any of them. Recent experiments have shown that the CHAGS are in some way involved in the interaction of cytotoxic T cells with their targets. In mouse and man reaction against a foreign MHC, for example in a mixed lymphocyte reaction, generates cytotoxic T cells⁵⁴⁻⁵⁶. In general the generation of such cytotoxic T cells requires cooperation between different populations of T cells: helper T cells which respond to differences in the I region (or HLA-D), and the cytotoxic T cells which respond to differences in the CHAGS^{59,60}. The cytotoxic T cells generated in a primary reaction of this type will kill target cells carrying the CHAGS to which they have been activated. In mice, for example, T cells activated to the H-2^a antigens will kill only target cells carrying an H-2^a CHAG at either the K or D region: the nature of the I or S regions is unimportant. Thus it seems that the CHAGS are the antigens with which such cytotoxic T cells interact. This restricted specificity of cytotoxic T cells must be a consequence of either a restricted range in specificities of the receptors for antigens on cytotoxic T cells (which seems unlikely) or a restriction imposed by the nature of the assay for cytotoxic function. In this context it is interesting that target cells lacking CHAGS can be killed by cytotoxic T cells only in the presence of concanavalin A (con A)⁶¹ a substance which may bypass the structures involved in normal recognition mechanisms.

It has been suggested that allogeneic responses are biologically important, for example, to prevent transmission of tumours between individuals⁶². However, the successful survival of inbred strains of animals makes a biologically important role for such reactions unlikely and they probably occur only in artificial situations. Consequently the fact that the antigenic targets of cytotoxic T cells generated in an allogeneic reaction are the CHAGS is of little general significance. In mice, however, it has also been shown that in reactions of cytotoxic T cells to surface antigens other than CHAGS, the nature of the K and D region gene products on the target cells is still vitally important. Cytotoxic T cells specific for a variety of different antigens have been used in these experiments including, (1) viral antigens on virus infected cells⁶³⁻⁶⁶, (2) histocompatibility antigens other than the K and D region molecules^{66,71}, and (3) haptens on chemically modified cells⁷²⁻⁷⁴. In each case the cytotoxic T cells are lytic only if the target to be lysed carries the specific antigen and also the same K or D region molecules as the original stimulating cells. For example cytotoxic T cells from H-2^k mice infected with vaccinia virus will kill H-2^k fibroblasts if they are also infected with vaccinia, but not virus-infected H-2^b cells. But because of the partial homology between certain CHAG alleles (as reflected in their shared public specificities) it is not sur-

prising to find a certain amount of cross reactivity in some cases^{66,69}. (This is also seen with cytotoxic T cells generated by an allogeneic reaction^{75,76}.) It is not at all clear why both stimulating and target cells for cytotoxic T cells must express the same K or D region molecules. It is even possible that the K or D region molecules involved in some of these cytotoxic reactions are not the CHAGS but products of closely linked genes^{57,58,67,68,75}. Further, it is possible that the effects seen with different antigens, although similar in appearance, are different in origin. This may be particularly true for hapten modified cells.

Two explanations have been put forward to explain the above phenomenon. The first is based on the proposition that the specific antigens cause a modification of the CHAGS. According to this theory, which is known as the "altered self" hypothesis, the modified CHAGS are the structures that are recognised by the cytotoxic T cells. For example, virus proteins on the surface of cells might combine with the CHAGS and the complex become the new antigenic determinant. Alternatively the viral proteins might interact with the CHAGS, causing the CHAGS to alter their shape and hence become foreign antigens. It is hard to imagine in molecular terms how these alterations are brought about, particularly when the specific antigens concerned are the minor transplantation antigens rather than viral proteins. The fact that about 10% of unprimed T cells react to all the antigens in a single foreign MHC⁷⁹ has led to the suggestion that T cell receptors are designed to react with foreign MHC antigens. This would support the "altered self" hypothesis, particularly if the modified CHAGS were to resemble the CHAGS found in other members of the species⁸⁰. It is not known, however, if unprimed cytotoxic T cells show a similar high percentage of reactivity to a set of allogeneic CHAGS.

The second explanation proposes that cytotoxic T cells require dual recognition of target cells through (1) specific antigen and (2) CHAG determinants to kill the targets. This hypothesis takes various forms depending on the nature of the proposed recognition of CHAG determinants. It now seems unlikely that this is through a requirement that CHAGS on cytotoxic T cells should be identical to those on their target. Thus H-2^k cytotoxic T cells prepared from H-2^k-H-2^d chimaeric mice infected with lymphocytic choriomeningitis virus, killed with equal efficiency H-2^k and H-2^d virus-infected target cells. Supporters of this type of dual recognition hypothesis can still argue that the important requirement is that the target cells should carry at least some of the CHAGS which were present at a critical stage of the maturation of the cytotoxic cell. The cytotoxic cells in a chimaeric animal would mature in the environment of H-2^d and H-2^k cells and hence kill both types of target.

Current opinion favours a dual recognition hypothesis in which cytotoxic T cells recognise their targets by two independently coded receptors, one of which reacts with the specific antigen and the second with a CHAG determinant⁸¹. By this hypothesis the restriction of cytotoxic T cells recognition lies in the narrow range of structures (CHAG determinants) with which the hypothetical second receptor reacts. It is difficult to visualise a molecular mechanism by which a family of receptors reacts specifically with CHAG determinants and no other antigens.

A third form of the dual recognition model hypothesises that a cytotoxic T cell recognises its target through a single receptor which reacts with specific antigen and, through cross reaction, with a CHAG determinant on the target. Some receptors on a cytotoxic T cell would react with the target through specific antigen while other identical receptors on the same cell would react with CHAG determinants on the target. This hypothesis implies that such dual interaction is not only important for cytotoxic

function, but necessary for the proliferation of cytotoxic T cells so that only clones carrying the appropriate cross-reacting receptors are selected.

In summary, much is still to be learned about T-cell recognition and cytotoxicity and no wholly satisfactory explanation exists for the restriction seen in these systems. It is not yet known if such restriction applies to cytotoxic T cells in man.

Introduction to the I region

The I region of the mouse and the region around the HLA-D locus in man have much in common. Both were initially studied by using a mixed lymphocyte reaction (MLR) as a means of detecting antigenic differences. (The so-called lymphocyte defined or LD antigens.) It is only recently that serological techniques have been applied to detect allelic forms of proteins coded by these regions. In the mouse it has been shown that these gene products are also involved in graft rejection and cell interaction; between T cells and B cells for the production of antibody, between different populations of T cells to generate suppressor cells, and between macrophages and T cells. The other important immunological phenomena associated with the I region are the immune response genes (Ir genes) which control the response to specific antigens. Ir genes have been found associated with the MHC in all species in which they have been looked for but so far in man the evidence for them is more circumscribed, mainly because immunisation with the appropriate antigen would be unethical. We will first discuss the biochemical properties of the products of the genes from this region and then their different biological properties.

Use of antisera to study the I region

Antisera specific for I region antigens have revealed several different antigenic systems on mouse B lymphocytes²². The antigens are also found on macrophages, sperm, epidermal cells^{22,23} and on some T cells, particularly T cells which have been activated by con A (refs 84-86). They are notably absent from erythrocytes and platelets. The different antigen systems are coded by different subregions of the I region, I-A, I-C and I-E and so on^{22,27}. The alleles of each system are described by a series of numbers representing individual determinants and studies on wild mice suggest that there may be private and public specificities as found on the CHAGS²⁴. In the inbred strains of mice not all the specificities have yet been assigned to I subregions and new specificities and I subregions are still being discovered. The term Ia antigens refers to all antigens associated with the I region. It is important to stress that the molecules carrying the numbered specificities described above represent only a part of the Ia antigens. For want of a better term we shall call the numbered Ia specificities the B-Ia antigens.

Membrane molecules have been isolated which carry B-Ia antigenic determinants²⁵. The specificities coded by genes in the I-A and I-C subregions are carried on different molecules^{25,26,27}. On the other hand the specificities determined by one allele from either subregion have so far been found on the same molecule²⁷. The molecules carrying the B-Ia specificities are glycoproteins each of which consists of two different polypeptide chains held together by disulphide bridge(s). It is not known if both chains carry antigenic determinants coded for by the I region. The molecules carrying the B-Ia determinants are not associated with β_2 -microglobulin on cell membranes.

There is a system similar to the mouse B-Ia antigens on human B lymphocytes²²⁻²⁷. Genes coding for these antigens seem to lie at several loci, at least one around the HLA-A locus and a second to the left of the HLA-B locus. In fact

one serum seems to show complete concordance with HLA-D typing²⁸, though this is not generally the case. This work is still at an early stage and it is not yet known how many loci are involved or the extent of the polymorphism. As yet there is no unified terminology for this system of antigens and although it has not been conclusively shown that they are analogous to the mouse proteins we shall call them the human B-Ia antigens. The existence of strains of mice which differ only in the I region and are otherwise genetically identical, makes it relatively easy to define mouse Ia antigens. In humans the absence of such defined genetic differences makes it very difficult to be certain that any anti-B-Ia antisera do not also contain activity to other unrelated antigens. The molecules carrying the human B-Ia determinants have not been definitely identified but from knowledge of the mouse antigens obvious candidates are the glycoproteins which contain two polypeptide chains which can be extracted from human B-cell membranes^{29,100}.

I region and the mixed lymphocyte reaction (MLR)

As we have already mentioned, differences in the I region evoke a 'strong' MLR²². This is measured by following the stimulation of DNA synthesis, after mixing lymphocytes from two different strains or individuals¹⁰¹. The cells which respond and proliferate are T cells¹⁰². Other regions in the MHC can cause an MLR but the response is usually much smaller¹⁰³. (In the mouse the M locus unlinked to the MHC can also cause an MLR¹⁰⁴.) The cells which are particularly adept at stimulating a response in an MLR are B-lymphocytes. Other cells including T cells, sperm¹⁰ and possibly epidermal cells¹⁰⁵ can also stimulate an MLR. In the mouse anti-B-Ia antisera directed against the stimulating cells will readily block their capacity to stimulate an MLR¹⁰⁶. Although it is notoriously difficult to interpret such experiments, it is natural to suggest the molecules carrying the B-Ia specificities described in the previous section are the molecules which are involved in stimulating the T cells which respond in MLR.

In man differences at the HLA-D locus provoke a strong MLR^{107,108} which has been exploited to type cells for this locus^{97,109}. The HLA-D locus shows balanced polymorphism but as yet the extent of the polymorphism is not known. The idea that B-Ia antigens evoke an MLR is again supported by the fact that one anti-human B-Ia antiserum reacts only with cells typed as HLA-D-DW3 by MLR⁹⁸. More usually, however, B-Ia antisera react not only with all cells with a particular HLA-D allele, but also with some cells carrying different HLA-D alleles; and some sera show no concordance with HLA-D at all⁹⁷. This type of result is difficult to interpret as HLA-D typing by MLR and serological typing may well have different sensitivities, and further because there is increasing evidence for cross reactivity between different HLA-D alleles⁹⁷.

I region and cell cooperation

The interactions between various cells of the immune system seem to depend on the compatibility of the interacting cells at the I region. Until recently, however, it was not clear whether that was because I region products played an essential part in cell cooperation, or simply because of an allogeneic reaction which abrogated cooperation. By the use of several techniques for eliminating the problem of allogeneic reactions, it has recently become possible to clarify the issue and it seems that I region products play an essential part in cell-cell cooperation, but that I region compatibility is not always necessary.

For example, cooperation between helper T cells and B cells in the production of antibody does not occur when the T and B cells are incompatible at the I region¹¹⁰⁻¹¹²,

unless an allogeneic reaction is prevented by the use of tolerant T cells^{113,114} or T cells selected for their inability to respond to I-region differences¹¹⁵. In interactions between antigen, macrophages and T cells it seems that I region products may play a part in recognition¹¹⁶⁻¹¹⁸. Helper T cells will produce a secondary response to an antigen-macrophage complex only if the antigen is presented on a macrophage carrying the same I region products as those on the priming macrophage^{117,118}. (In this case the effect of histocompatibility reactions have not been fully investigated.) It is now possible to circumvent the complications arising from allogeneic reactions altogether by using soluble T-cell factors to study the control of the immune response.

These factors fall into two classes. First, there are antigen specific factors which bind to their corresponding antigens and lead to specific responses¹¹⁹. Second, there are non-specific factors which are induced by antigens¹²¹, mitogens (O. Sjöberg, unpublished) or an MLR^{122,123}, which enhance an antibody response to certain antigens¹²⁴. The antigen specific helper factor is not classical antibody and at least part of it must be coded for by genes in the I region since it reacts with anti-Ia sera¹²⁵. Treatment of B cells with anti-Ia antiserum prevents the cells from absorbing factor, which implies that at least parts of the B-cell acceptor sites for the T-cell factor are also coded by genes in the I region¹²⁶. Thus two different, but interacting, products of the I region are involved in T-B-cell cooperation. Preliminary evidence suggests that the acceptor molecule carries the B-Ia determinants and it may be the acceptor molecules that are responsible for stimulating an MLR. All that is known of the antigen specific factor is that it is a glycoprotein of molecular weight about 50,000. So far no allogeneic barrier has been found for the helper factor¹²⁸ and indeed mouse factor will work with human lymphocytes¹²⁷.

A second similar, but not identical, antigen specific factor is involved in T cell-T-cell interactions in the generation of suppressor T cells¹²⁹⁻¹³¹. The factor binds to antigen, reacts with anti-Ia sera but not anti-immunoglobulin sera and has a molecular weight of approximately 50,000. The factor is absorbed by T cells but not B cells¹³². This suppressor factor shows certain allogeneic barriers in that factor from one strain of mice will not react with all other strains. It has been suggested that the ability to absorb the suppressor factor is also related to I region products which mean that the I region is involved in two systems of interactive gene products important in regulation of the immune response¹³². It is clear that suppressor and helper systems are different but it is quite possible that they share genetic elements.

These antigen specific factors are likely to be closely related if not identical to the actual receptors for antigen on T cells. It has so far proved extremely difficult to characterise unambiguously antigen receptors on T cells, particularly as T cells will absorb serum antibody^{133,134}. By using antisera which react with idiotype determinants on the variable region of immunoglobulin heavy chains it is possible to obtain evidence that an antigen receptor on T cells contains at least parts of heavy chain variable regions^{135,136}. To date there is no evidence that the antigen specific factors described above contain any part of immunoglobulin molecules, including the variable regions. Other factors which may be important in the regulation of the immune response, do react with anti-immunoglobulin antisera^{137,138}. There is no simple way to explain these apparent contradictions concerning the nature of the T-cell receptor for antigen but it is clearly important to find out the exact chemical nature of these antigen specific factors.

There are several ways that lymphocytes can be provoked into producing a nonspecific factor which can enhance the response of B cells to particular antigens. One factor with this activity seems to be a complex of β_2 microglobulin and

Ia antigens^{133,139} though other functionally similar factors produced differently do not react with anti-Ia sera (ref. 140 and A. Schimpl and E. Wecker, personal communication). The relationships of these nonspecific factors to each other and to the specific factors are not known.

Immune response genes

The discovery of immune response (Ir) genes in the MHC is extremely important and has acted as the catalyst for much of the work on the I region. It is known that certain individuals within a species fail to respond to a specific antigen and this deficiency maps within the I region. So far, in different mouse strains, defects have been found in the response to more than 40 antigens. The Ir genes controlling these responses lie in all three subregions of the I region. In every case the absence of response is recessive—that is, response is dominant^{141,142-143}. Further analysis of these defects has revealed that for at least some of these antigens there exist at least two Ir genes which can complement each other^{129,144-149}. Thus in some cases the hybrids between two strains which do not respond to a particular antigen may themselves respond. The existence of complementation groups suggests that at least two types of I region product are necessary for an immune response. The antigen specific factor and its acceptor described in the previous section are obvious candidates as products of a complementing gene system and indeed with certain antigens there is some evidence to support them^{129,150,151}. Similarly it has been found that there are at least two complementation groups for the generation of suppressor T cells^{132,152}. I region products have been shown to be involved in the regulation of the response to a wide variety of antigens though Ir gene defects are only seen for antigens which carry a restricted number of determinants. This suggests that responses to complex antigens involve the products of several complementing systems. Defects in a component of one system need not affect the activities of the others.

There are many immune response genes which are not associated with the MHC, some of which have been mapped to particular loci. Recently it has been shown that the products of one of these other Ir-genes is important for the interaction of antigen specific helper factor with B cells¹⁵⁰.

The complement system and the MHC

There are genes in the MHC which affect the complement system, a series of serum proteins activated characteristically by antibody-antigen reactions. These genes may function two ways. First, as structural genes which code for certain of the complement components. The most convincing evidence for this comes from linkage studies of allelic variants of certain complement components. Second, there may be a gene or genes which control the level of certain complement components. The first indication that genes affecting the complement system lay within the MHC came from work on the mouse Ss-Slp system. Ss and Slp determinants are found on two serum proteins whose levels are affected by sex hormones and by genes in the H-2 region, now mapped between I and D¹⁴¹. Anti-Ss antiserum was shown to inhibit complement mediated haemolytic activity of mouse serum¹⁵⁴ and it now seems that Ss protein is mouse C4 (refs 155 and 156).

In man and rhesus monkey several allelic forms of factor B can be detected by electrophoresis. The genes coding for these variants are linked to the MHC^{157,158}. The structural gene in man for factor B has been tentatively placed to the left of HLA-B¹⁵⁹. Since factors B and C2 have analogous properties in the alternative and classical complement pathways and very similar physicochemical characteristics it has been suggested that the structural genes for these proteins are tandem duplicates¹⁶⁰. Recent evidence suggests that the C2 electrophoretic variants are indeed

linked to the MHC¹⁶⁰. Structural genes of this type, lying within the MHC, may be useful for understanding the pressures which generate balanced polymorphism at other loci. If these pressures operate on the MHC as a whole one would expect to see balanced polymorphism in complement components coded for by MHC genes. This would only be true if such complement components were able to accommodate sufficient structural changes and remain functional. So far only four functional alleles of factor B have been found, two of them uncommon¹⁶¹.

In addition to the structural genes for complement components in the MHC there may be genes which control the serum levels of these components. The Ss-Slp system may contain this type of gene. Deficiencies of particular complement components could represent either deletion of structural genes or malfunction of a controlling gene. In man C2 deficiency is linked to HLA in a number of family studies and seems to be in linkage disequilibrium with the haplotype A10-BW18¹⁶²⁻¹⁶⁵. Deficiencies of C4 and C8 have also been found to be linked to particular HLA haplotypes although only one family has been studied in each case¹⁶⁶. If these deficiencies represent malfunction of genes controlling the levels of complement components then it is possible that only one such gene exists in the MHC and that this gene may also be responsible for the observed MHC influence on levels of the receptor for complement components on lymphocytes¹⁶⁷. Naturally not all the genes for the complement system lie within the MHC C3 and C6 electrophoretic variants in man^{168,169} and Clr (man)¹⁷⁰ and C5 (mouse)¹⁷¹ deficiencies are unlinked to the MHC.

MHC and disease

Many diseases in humans have an association with particular CHAGS¹⁷². These associations can be divided into four types, each of which may have a different origin.

(1) The only very strong association is that of HLA-BW27 with ankylosing spondylitis and a related group of diseases. About 95% of Caucasian patients with ankylosing spondylitis have this allele¹⁷³⁻¹⁷⁵. It is likely that the cause of this strong association lies in a property of the BW27 protein itself, particularly since it is found in other racial groups^{176,177}. There are various ways in which CHAGS might directly influence the susceptibility to disease. For example, they could function as receptors for viruses or they may resemble certain pathogens so closely that the animal is unresponsive to that pathogen through self-tolerance^{7,92}. The absence of BW27 in a few patients with ankylosing spondylitis is still compatible with the theory that the BW27 protein is directly involved in susceptibility to the disease. Ankylosing spondylitis is a multifactorial disease, and in the BW27 negative patients there may be an excessive accumulation of the other factors involved.

(2) There can be weaker, but still significant associations of diseases in the general population with individual CHAGS, for example thyrotoxicosis and some other autoimmune diseases with B8 (ref. 178) and psoriasis vulgaris with BW17 (ref. 179). A weak association would be expected if the genes responsible for increased susceptibility were closely linked to the CHAGS and remained with particular CHAG alleles through linkage disequilibrium. However, these diseases could be multifactorial and the CHAGS themselves may be one of the factors directly involved in increased susceptibility. In this case as with ankylosing spondylitis one would expect to see the same CHAG allele involved with the disease in studies of different races.

In general if immune response genes are the reason for the observed associations, an allele leading to an absence of response would only have a deleterious effect in homozygotes as response is dominant. On the other hand, alleles which lead to an excess, or normally unwanted, response

would be dominant in heterozygotes. The diseases in the categories discussed above are in general not found with greater frequencies in MHC homozygotes. Consequently non-responder alleles are unlikely to be responsible for disease association. Many of the diseases in these two categories have an auto-allergic element which would be expected if the deleterious Ir-genes lead to an autoallergic response.

(3) A third category of association of CHAGS with disease are those cases in which there is a higher frequency of particular CHAGS among individuals with greater resistance to particular conditions. For example, there is a higher than average proportion of HLA-A2 positive individuals among long term survivors of acute lymphocytic leukaemia¹⁸⁰. This association may again be due to a rare responder allele of an immune response gene linked to HLA-A2 but in this case the response is beneficial. Linkage to beneficial responder alleles could also be responsible for the observed low proportion of particular CHAGS among individuals suffering from certain conditions¹⁸¹ (for example HLA-BW15 and chronic viral hepatitis)¹⁸².

(4) Finally, it is possible to find a particular CHAG associated with a disease within a family though not in the general population. For example in ragweed allergy sensitivity is inherited in particular families together with an MHC haplotype¹⁸³. In this situation the gene involved is unlikely to be a CHAG gene but some linked gene, again probably an immune response gene.

In all cases if the association of disease to CHAGS is through linked Ir genes it is sensible to look for associations with other markers in the MHC. Several studies have used the HLA-D locus for this purpose^{93,184}. In many cases association with HLA-D is stronger than with CHAG. This would be expected if the important genes were the Ir genes providing the relative distribution of MLR and Ir genes is the same in man and mouse. However, there are many immune response genes and their exact distribution is not known, even in the mouse, so that diseases most strongly associated with the CHAG could in fact be explained by close linkage of an Ir-gene. It is also possible that several genes in the MHC influence susceptibility to a single disease. Under such circumstances one would expect to see the disease associated more strongly with a haplotype than with individual markers¹⁸⁵.

Finally, in a few cases the association of disease with the MHC is probably a consequence of defects in the complement genes. For example, systemic lupus erythematosus is found associated with C2 deficiency and hence with the haplotype A10-BW18¹⁸⁶.

Coda

It should be clear from what we have written that there is still much to be learnt about the MHC and it is probably premature to attempt a rational synthesis of all the facts. Phenomena which need to be explained are the balanced polymorphism at some loci, linkage disequilibrium, and the biological function of the CHAGS and determinants responsible for an MLR. In addition, the implications of the maintenance of these immunologically important genes in one complex during evolution are not understood.

It is possible to construct a moderately coherent explanation of the facts with the products of the immune response genes playing a central role. As these genes are codominant and it is usually desirable to minimise the number of determinants to which an individual cannot respond, there will be heterozygous advantage. This is particularly true if the number of immune response genes approaches the limit for stable tandem duplication. This accounts for balanced polymorphism of immune response genes which could be transmitted to the CHAGS through linkage dis-

equilibrium, provided that CHAGS can accommodate many amino acid replacements without losing whatever biological function they have. The balanced polymorphism of the CHAGS might simply be a consequence of their linkage to the Ir genes and have no relationship to their own biological function.

The properties of the products of the I region could also account for linkage disequilibrium. The fact that products from separate immune response loci in the MHC have to react with each other to control the immune response would lead to a selective advantage to the transmission of pairs of alleles together as a haplotype.

The above synthesis does not explain why genes for complement components are found in the MHC, nor does it cope with the particular attention T cells seem to pay to the CHAGS in all cytotoxic reactions. An alternative explanation of polymorphism is that the CHAGS are involved in developing T-cell immunity to viruses and other pathogens¹⁸⁶. It has been shown that heterozygosity of the CHAGS on virus infected target cells increases the efficiency of T-cell cytotoxicity. There are many other ways by which pathogens can be recognised and dealt with *in vivo*, which will reduce the pressure for heterozygosity of the CHAGS. Although this model ascribes a biological function to the CHAGS it does not explain linkage disequilibrium or their association with Ir genes, nor is there at present any clear understanding of the mechanism by which antigens on virus-infected cells become associated with the CHAGS.

If the CHAGS act as the actual receptors for viruses, it is possible to give an alternative explanation for linkage disequilibrium¹⁸⁷. Any individual with a receptor for a particular viral pathogen will be at risk especially if that person does not carry the appropriate immune response gene, for resistance. Thus pairs of alleles will be encouraged to travel together—a CHAG allele and the appropriate immune response gene. Linkage disequilibrium in the intervening piece of DNA will ensue. There may be other structures in the MHC which act as virus receptors¹⁸⁸.

It is obviously important to know if the nature of the genes clustered together in the MHC is of some significance and has therefore been conserved in evolution. It is at present hard to imagine why particular genes are clustered together. It has been suggested that the MHC has evolved by tandem duplication from the *T/t* complex¹⁸⁹. The possible similarities between molecules from the *T/t* complex and H-2 complex lend weak support to this unlikely idea. It is obviously too early to say what relevance the *T/t* complex may have to the MHC and indeed it is really too early to promulgate any further unsubstantiated speculation.

We thank our many colleagues for their comments. S.B. is grateful to the Leukaemia Research Fund for financial support.

Radio-echo layers and the recent stability of the West Antarctic ice sheet

I. M. Whillans

Institute of Polar Studies and Department of Geology and Mineralogy, The Ohio State University, Columbus, Ohio 43210

A new method for studying polar ice sheets confirms the generally accepted concepts of ice sheet flow and finds that a region near the ice crest of the West Antarctic ice sheet has been stable for ~ 30,000 yr.

A CHANGE in the mass or configuration of the large continental ice sheets could affect world sea level, alter the average albedo of the polar regions, and change the climate^{1,2}. To determine whether the ice sheets have changed, are changing, or are likely to change in an im-

portant way, and to allow the interpretation of palaeoclimatic results of studies of deep cores it is necessary to understand the history and dynamics of ice sheet flow.

One way to study the present-day balance of an ice sheet is to compare data on ice movement with surface mass-balance (new snow accumulation) data. This can be done by comparing measured changes in the elevation of markers in the surface with local surface mass balance^{3,4}, or by comparing the horizontal flow of ice with the rate of up-glacier replenishment by new snowfall⁵⁻⁹. In general, however, the interpretation of such studies is difficult because

Fig. 1 Example of radio-echo record. A profile ~ 16 km long is represented. This example is located ~ 70 km from Byrd Station (Fig. 2), where the ice is $\sim 2,500$ m thick. Stars indicate the layers selected for analysis.

of uncertainties in measurement or because deep ice velocities are not known. A more satisfactory method for determining the health of an ice sheet is needed.

The recent histories of the Greenland and Antarctic ice sheets have been discussed using profiles of ice temperature¹⁰⁻¹², total gas content¹³⁻¹⁵, and ratios of the stable isotopes of hydrogen or oxygen¹⁶⁻¹⁸. Although very valuable, none of these techniques can distinguish clearly between changes in the form of the ice sheet and climatic changes.

A new approach is described here for studying the present and past dynamics of large ice masses. The method combines measurements of surface mass-balance, surface strain-rate, and the form of internal layering in the ice sheet determined by a radio-echo sounding technique.

Method

During the austral summer 1974-1975, radio-echo sounding flights were conducted in the Antarctic¹⁹. Equipment, designed and built by the *Danmarks Tekniske Højskole* (Lyngby, Denmark), and operated by members of the Scott Polar Research Institute (Cambridge, UK), was flown in an LC-130 (Hercules) aircraft by the US Navy as part of the United States Antarctic Research Program. Figure 1 is an example of a record from these flights: it shows radio reflections not only from the surface and base of the ice sheet, but also from within the ice mass. Many of these internal layers can be traced horizontally for >170 km. It has been suggested that the internal reflections are associated with sedimentary variations in density or impurity content, or old refrozen melt layers²⁰⁻²³, with certain annual layer spacings, or with horizons at which the mean ice crystal orientation changes²¹.

Flights were made along and perpendicular to the axis of the Byrd Station Strain Network (BSSN), which is up-glacier from Byrd Station, Antarctica (Fig. 2). Surface velocities and surface mass balances have already been measured along the BSSN^{9,24}, and using these data, it is possible to calculate the depths of ice layers that were deposited at different times in the past. The form of these buried layers is compared here with the internal layering revealed by the radio-echo sounding.

The model

A very simple model for the flow of the ice sheet is used. It is assumed that the strain rates, as measured at the surface, are constant throughout the thickness of the ice mass, but they vary in horizontal directions. The ice sheet is initially assumed to be in a steady state (with ice thicknesses and velocities independent of time), but possible departures from the steady state can also be discussed. The model

cannot adequately describe the flow of ice over and around variations in the bed, but is conceptually simple and adequate for present purposes.

According to the model, the horizontal velocity of a vertical column of ice is the same at all depths, and variations in the bed of the ice sheet do not generate strains within the ice sheet except those that are measured at the surface. A layer of snow deposited at the surface, after compaction to ice, becomes buried by later accumulation, is thinned by the extending flow, and is carried down-glacier as the ice sheet flows towards the sea. The depth of a layer of any age may thus be calculated, and unlike the rather similar models of Robin and others²², and Harrison²¹, ice thickness and bottom topography are not used in the computation.

The model results and the radio-echo results are independent and the model was developed before the radio sounding flights were conducted. The strain rate and velocity, as measured at the surface, are, in part, physically determined by ice thickness and bottom topography, so that some correlation between calculated buried layer form and the base of the ice sheet is to be expected for larger scale features of the relief.

Model—layering agreement

Figure 3 shows a profile of the ice sheet along the axis of the BSSN. The data for the depth calculations come only from surface measurements along the BSSN. The calculated isochrons and the measured radio-echo layering show agreement that is much too good to be coincidental, confirming the results of a similar study made along a flowline in northern Greenland²². This shows that the simple ice-flow

Fig. 2 Antarctica, showing the location of the network (short straight line), Byrd Station (BS), and the Amundsen and Ross Seas (A and R).

model is a good approximation for the flow of the ice sheet, supports the concept that the radio-echo layers are connected with the depositional stratigraphy, confirms the conclusion that, at present, this part of the ice sheet is almost in a steady state⁹, and, finally, indicates that this portion of the ice sheet has been close to its present form for a long time: probably >30,000 yr.

The confirmation of the ice-flow model is important. Ice flow at depth can be taken to be in the same direction as the surface velocity; there is important horizontal flow to at least the depth of the deepest recorded radio-echo layer; and the strain rates measured at the surface can be applied through most of the thickness. The model has wide acceptance in the literature but there are few other tests of its validity for an ice sheet. Perhaps the best partial test so far arises from the measurement of the inclination change of the Byrd Station hole²⁶, which showed that the ice velocity vectors under Byrd Station lie close to a single plane, and that there are no sudden changes in shearing rate. This is for just one site, however, and the inclination changes could be measured only for the upper 1,490 m of the ice sheet.

Fig. 3 Profile along the axis of the BSSN. Three internal reflection layers and the base of the ice sheet have been obtained from the radio-echo records. The dotted lines show the calculated positions of ice layers of the ages specified. The ages have been selected so that the isochrons are at the same general depth as the selected radio-reflecting layers.

Analyses of the temperature distribution in ice sheets also find that a steady-state, uniform strain-rate model of flow similar to that used here can describe the measured temperature profiles. Changes in the glacier regime that may have occurred more than several thousand years ago may not, however, be detected by the temperature analyses, and differences in flow direction or vertical strain rate between the upper and lower portions of the ice mass may not greatly affect the agreement of the calculated and the measured temperature profiles.

The success of the model is important to studies that have been conducted with data from the deep core hole at Byrd Station. The ice-flow model used in the analysis of the temperature profile¹¹ and the depth-age relationship for the ice core as calculated by some workers^{17,18} are confirmed. The depth-age relationship obtained from microparticle layering²⁰ is not, however, consistent with the results presented here. Perhaps the microparticle layering is not annual^{17,20}, as was assumed in that work.

The radio-echo layering and the isochrons do not agree exactly. To a large extent this may be because the strain network and the flight lines are in slightly different positions. The depth of the layering is variable in the third dimension, as shown by the results of flights perpendicular to the BSSN axis, and a small navigational error could explain the discrepancies between the radio-echo layering and the isochrons between 0 and 40 km in Fig. 3. Down-glacier from 120 km disagreement is believed to arise from sub-surface advection⁹ associated with the change in flow direction beginning at 140 km, and after 140 km the model calculations are not valid, because the strain network does not follow the flowline. Smaller differences between the model and the radio-echo layering are associated with irregularities in the bed, a factor that is not adequately treated by our simple model.

Each radio-echo layer is probably not caused by a single physical surface within the ice sheet^{21,22}. Sufficiently large changes in permittivity or loss tangent are probably too infrequent to cause all the layering in Fig. 1. More likely, the combined effect of many small changes in permittivity or loss tangent within the ice sheet causes each single layer on the radio-echo record. Each radio-echo layer may be associated with material injected into the atmosphere, perhaps from a volcanic eruption, and the material was for many years seasonally deposited on the ice sheet according to seasonal shifts in weather patterns^{19,22}.

Other explanations for the success of the model?

We suggest that the radio-echo layering is associated with stratigraphic layers of certain ages, but it could also be argued that the radio returns are associated with certain spacings in stratigraphy²¹; for example, annual layering. This spacing would be related to the wavelength of the radio wave in ice, such that reflections from all, or many, of the annual layers would be in phase, and therefore reinforce each other. Using the simple steady-state model for ice flow described above, the depth at which the annual spacing is equal to certain selected values has been calculated and is shown in Fig. 4. The upper two radio-echo layers do not correlate well with these contours and the possibility that only certain annual layer spacings cause the radio reflections is discounted.

Except for the probably small influence of bottom melting or freezing, the oldest isochrons and the thinnest annual layer spacings should both be near the base of the ice sheet, so that very old isochrons and contours of very thin annual layer spacing should be similar, and the fair agreement of the 0.03-m contour in Fig. 4 with the deep radio-echo layer is expected.

It may also be argued that the radio-echo layering is caused by ice foliation²¹ from shearing flow in the ice sheet. This is plausible because bands of different crystal size and crystal orientation are reported for the Byrd Station core²³. Foliation, however, does not become well developed until deeper than 1,250 m below the surface (300 m a.s.l.) at Byrd Station (at 162 km in the Figs)²³ and the radio-echo layering is well developed above this level (Fig. 1). Furthermore, near-horizontal foliation is not likely to have been strongly developed in the ice crest region where horizontal shear strains are orders of magnitude less than elsewhere, yet the radio-echo layering continues, uninterrupted, across the ice crest (at 0 km in Figs 3 and 4). The simplest explanation for the radio-echo layering is that they are isochrons.

Values for surface mass-balances and strain-rates other than those that have been measured could be used to calculate the isochrons. Agreement between the isochrons and the radio-echo layering would be equally good for values of surface mass-balance and strain rate that retain a constant proportion to the measured values (although the calculated ages of the layers at any depth would differ).

There are two distinct surface mass-balance regimes along the BSSN: the first, near the ice crest extending to ~40 km, has a larger surface mass-balance that decreases smoothly with distance from the Amundsen Sea; and the second region, the remaining 120 km, has a smaller surface mass-balance that varies according to the surface slope²⁴. The surface mass-balance is therefore determined by processes acting with different effectiveness in the two regions, so that the climate is unlikely to have changed in such a fashion as to affect both surface mass-balance regions in the same proportion. For example, a change in the frequency of snow-bearing storms from the Amundsen Sea would be expected to affect the surface mass-balance of the ice crest region more than elsewhere along the BSSN. This would change the relative depths of each isochron under the two surface mass-balance regimes and result in a poor correlation with the radio-echo layering.

Fig. 4 Profile along the axis of the BSSN. As in Fig. 3, the radio-echo layering is shown by solid lines, but the dotted lines are the calculated positions of ice with the specified annual layer spacing. This is a test of the hypothesis that the observed radio-echo layering may be caused predominantly by the constructive interference of many weak reflections from certain regular spacings in the annual stratigraphy.

A uniform thickening or thinning of the ice sheet with time would change the mean strain rates in a constant proportion, but it is difficult to conceive a mechanism that would thicken or thin the ice sheet uniformly and significantly. Changes in surface mass-balance or air temperature would cool or warm the ice mass at different rates and by different amounts in different parts of the ice sheet, and thus cause important changes in flow lines and dimensions of the ice mass. Similarly, shifts in the position of the ice crest, caused perhaps by changes in the grounding zone, where the ice sheet begins to float in the Amundsen Sea or Ross Sea embayments, would affect the surface mass-balance distribution, and the flow directions and consequently the positions of the isochrons in the ice sheet. Changes at the seaward edge of the ice sheet would affect different drainage basins differently and cause shifts in the position of the ice crest: such a shift would have disturbed the layering of Fig. 3. The radio-echo layering in the BSSN region is consistent with the present-day flow pattern and surface mass-balance distribution and it is very improbable that a major change in flow or precipitation pattern could have resulted in internal layering that so closely follows present-day steady-state isochrons.

Ice sheet stability

The simplest and most plausible explanation for the simi-

larity of the calculated isochrons and the radio-echo layering is that the mass-balance, velocity field, and shape of the central portion of the ice sheet have not changed significantly during the past ~30,000 yr. Small changes in the surface mass-balance or strain rate may not be detected by the technique. The correlation of Fig. 3 is almost equally good using surface data locally changed by as much as ~5% from present-day values.

Other workers have suggested that the West Antarctic ice sheet is behaving unstably²⁴⁻²⁶, but we find that there have been no important changes in the past 30,000 yr. Peripheral parts of the ice sheet could, however, have recently begun retreating rapidly^{27,28}, or have begun advancing rapidly², without the effect having yet reached the region of the ice crest, and we cannot predict future behaviour. The significance of the stability conclusion extends beyond the immediate BSSN region because distant thickness changes would have altered flow directions in the BSSN region and would appear as anomalies in the radio-echo layering. It is difficult to estimate over what area the steady-state result is applicable, but it probably extends 300 km from the BSSN, or over most of Marie Bryd Land.

The technique described here could be applied to other areas where the ice flow can be simply interpreted and where internal radio-reflections can be obtained. It should be used to help select sites for deep drilling and aid in the interpretation of deep core data, and, as shown here, it can be used to determine the balance at present and in the past (since ~30,000 yr BP, in this case) for a large ice sheet.

We thank the NSF for support. Colleagues at the Scott Polar Research Institute (Cambridge, UK) provided the processed radio-echo records and flight data. Part of the analysis was done while the author was a guest at the Geophysical Isotope Laboratory, University of Copenhagen (Denmark). Thanks are extended to C. Bull, D. J. Drewry, D. H. Elliot, N. D. Hargreaves, S. J. Johnsen, J. H. Mercer, C. S. Neal, G. de Q. Robin, L. G. Thompson and the referee for helpful discussions and reviews of the manuscript.

Alternating subduction direction and the evolution of the Atlantic Caledonides

A. E. Wright

Department of Geological Sciences, University of Birmingham, PO Box 363, Birmingham B15 2TT, UK

The Morarian, Celtic, Grampian and Lakelandian orogenies are the result of alternating subduction north-westwards and then south-eastwards successively from 1,000 to 450 Myr at the margins of one major ocean basin. Subduction on both margins between 450 and 350 Myr caused the final closure of the basin and the Caledonian orogeny.

THE late Precambrian and lower Palaeozoic history of the north Atlantic region has been difficult to unravel in terms of plate tectonics largely because of the large number of apparent orogenic events and their differing ages in different segments. Most attempts have followed Wilson¹ by starting the history of the Caledonian system with an assumed phase of continental splitting to form the Iapetus² ocean at the beginning of the Cambrian. This separated north-west Scotland, north-west Ireland, and western Newfoundland from England, Wales, south-east Ireland, and E Newfoundland. Such an ocean must have existed at least from Cambrian times, as has been demonstrated³ on palaeontological grounds, but when the late Precambrian history of the region is studied it becomes very difficult to find unequivocal evidence of initial continental rifting. Alkaline activity at 565 Myr in the St Lawrence and Oslo Graben has been suggested⁴ as indicative of the initial rifting of the continental mass. Early Cambrian fossil assemblages from the American and Welsh areas, however, represent highly contrasted benthic faunas which presumably lay on opposite sides of a well developed ocean^{5,6} so it seems unlikely that the time of initial opening was as late as 565 Myr. The most significant feature of the ocean, however, that is difficult to reconcile with a repeated closing and opening, is the independent nature of the plate tectonic events taking place on either margin from 1,000 to 350 Myr.

I suggest here that Iapetus was an ocean of long standing. The successive climactic episodes of orogenic activity (deformation, metamorphism and some types of volcanic and plutonic activity), although nowhere precisely dated, do seem to fall into a remarkably consistent pattern of alternating activity on the north-west and south-east margins. Iapetus presumably had a spreading ridge along its axis, and I suggest that subduction took place alternately to the north-west and south-east, the subduction stopping after a climactic 'orogenic' phase and then transferring to the far side of the ocean. The known pattern of orogenies are thus produced in alternating sequence.

The cause of each orogenic episode then becomes the principal problem. It has recently been recognised that marginal basins may be important in the plate-tectonic evolution of orogenic belts and the Burlingtonian orogeny in Newfoundland has been ascribed⁶ to the closing of a marginal basin. The sequence of events recognised⁷ in the Andean chain of southern Chile seems a likely model. There a cordilleran orogenic belt split behind the subduction zone and a series of marginal basins of oceanic material formed behind a continental sliver. Subsequent closure of those basins was accompanied by considerable compressional

deformation and the subduction in that area probably ceased soon afterwards. The reasons for the marginal basin closure and cessation of subduction have not, so far, been deduced.

A model for the development of the orogenic phases is suggested here (Fig. 1a-d) whereby subduction under a continental edge may lead to the development of a marginal basin beyond the volcanic arc/continental margin which eventually closes and causes an arc/continent collision orogeny. The subduction direction then changes to the far side of the major ocean. This produces a pattern of alternating activity on either margin, which is illustrated for the Caledonian of the North Atlantic by a series of five cartoons which portray the situation immediately preceding each of the following five orogenic events:

- (a) The Morarian⁸ before ~ 1,000 Myr.
- (b) The Celtic⁹ and Ganderian⁸ at ~ 600 Myr.
- (c) The Grampian¹⁰ and Burlingtonian⁶; Tremadoc-Arenig in age.
- (d) The Lakelandian¹⁰ somewhat similar in age to the Taconic of the Appalachians; Upper Ordovician in age.
- (e) The Caledonian or Cymrian¹⁰ orogeny; end Silurian to mid-Devonian from Scandinavia to Newfoundland. This marks the final closure of Iapetus.

The Morarian orogeny

The earliest evidence of continental margin activity on the site of Iapetus comes from north-west Scotland (Fig. 2). The deposition of the Stoer Group¹¹ at ~ 1,000 Myr may mark a post-orogenic molasse deposition to the Morarian orogeny. The Moinian¹¹ lay to the south-east and is a series of trough greywackes, the current markers indicating currents running north-west-south-east. In places it can be seen lying directly on Lewisian basement. It was involved in one or perhaps two periods of deformation¹² and the climax of metamorphism produced a migmatitic core at 1,050 Myr (ref. 13). Later pegmatites were intruded at ~ 730 Myr (ref. 14). The folds include large scale nappes whose direction of transport was probably towards the south-east, and the grade of metamorphism and the ductile deformation of both the crystalline Lewisian and the Moinian sediments suggests that there was a collision orogeny in this region ~ 1,050 Myr ago. This has been termed the Morarian⁸.

A similar event has been recognised in the Ox Mountains inlier of north-west Ireland^{14,16}. The Deer Park Complex of Clare Island has associated amphibolites and serpentinites which continue to the east and north into the Ox Mountains area¹⁶. They are considered to be older than the upper Dalradian and may thus represent part of a Morarian Suture Line. They lie between the possible continuation of the Great Glen Fault and the Highland Boundary Fault—possibly in part even to the south-east of the latter. It thus seems from this evidence that the Morarian metamorphic belt extended south-east of the Great Glen and forms the basement to the Dalradian Supergroup.

It is thus suggested (Fig. 2) that the Moinian developed on the continental margin behind an island arc, and was deposited some way landward of the subduction zone and

any associated igneous activity. The collision of the island arc with the margin of the continent is envisaged as the cause of the Moravian orogeny.

Elsewhere in the North Atlantic region this was the time of the Grenvillian and Riphean orogenies. Both of these areas are characterised by the apparent lack of an extensive depositional episode and the high grade, in places granulite

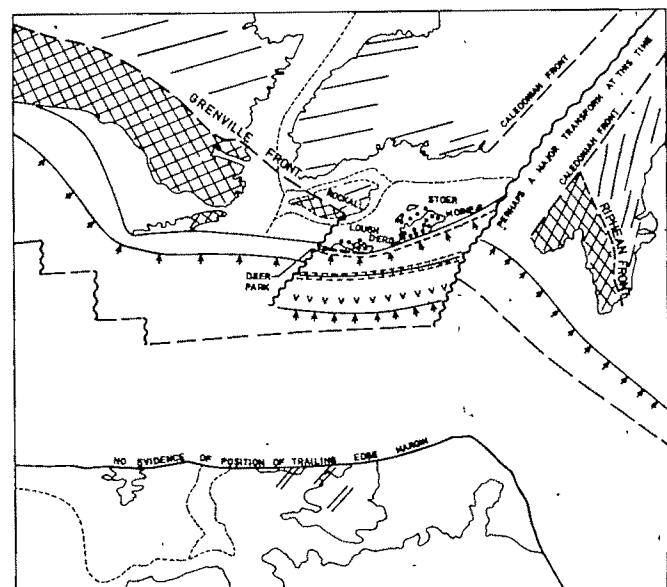

Fig. 1 *a*, Subduction with trench and trough sedimentation (*A*) leads to development of volcanic arc (*B*) either on continental crust thinned by the initial rifting (as shown) or on oceanic crust. Some time after the initiation a marginal basin (*C*) forms behind the volcanic arc and continental margin shelf sediment develops on crust thinned by marginal basin formation (*D*). *b*, Arrival of hot light crust, *A* (mid-ocean ridge) at subduction zone (*B*). This is too light to subduce. Provided that the marginal basin is not too young (that is, its older parts are relatively cool) subduction is initiated within the marginal basin either at *C* or *D*. Sediments at *C* (or *D*) become trough sediments and may be raised to blueschist facies. Cessation of the main subduction causes the marginal basin spreading centre to become a dead ridge (*E*). By this time the far side of the ocean (*F*) has a thick shelf sequence on the trailing edge of the continent. *c*, Subduction within the marginal basin causes collision of the volcanic arc with continent at *A* with nappes on to continent (*B*) and probably on to arc (*C*). Ophiolite (of marginal basin type) and blueschist fragments may be caught in suture zone (*D*). Original trench zone (*E*) now becomes site of shelf sedimentation as this is now a trailing edge, the mid-ocean ridge (*F*) now moving away from this continent toward the subduction zone (*G*) now on the far side of the main ocean. *d*, After the stopping of subduction and orogenesis at *A* (by a sequence similar to *a-c* above) subduction again starts at original side (*B*) and a new marginal basin (*C*) would be initiated in the thinner crust of the original volcanic arc which has been rapidly eroded and covered with shelf sediments (*D*). The new volcanic arc (*E*) may be partly on the older arc or further oceanwards, but is likely to be a good deal nearer the ocean than the original orogenic collision zone (*F*).

facies, metamorphism of early Proterozoic rocks. Anorthosite plutons seem characteristic of this belt and late orogenic granitic bodies as late as 850 Myr occur in Telemark¹⁷ and Sweden. The Grenville front, which probably extends across the Rockall Bank¹⁸, is approximately at right angles to the Riphean front on Bullard, Everett and Smith's reconstruction of the North Atlantic¹⁹. Certainly neither the Grenville nor Riphean fronts represents a suture line, though there may be such within the central parts of these complexes. Thus, although the recent determination of a 'Grenvillian' age for the Moravian high grade metamorphism²⁰ is indicative of orogenic activity at the same time as the Grenville and Riphean events it seems unlikely that the Moravian represents a simple continuation of the Grenville to link it with the Riphean. It may be that south-eastern Scandinavia was at this time on the northerly side of Iapetus (Fig. 2) and that the ocean passed south-eastwards into mid-Europe between Scandinavia and the Low Countries, but evidence is lacking in this critical area. In any case the position of the Moravian seems rather anomalous regarding the amount of sedimentation and the type of deformation. Perhaps the Scottish and Irish areas represented a small back-arc basin to the main Grenvillian-Riphean orogenic belt which elsewhere developed as a Cordilleran orogeny largely by reworking of continental crustal material and without a significant sedimentary prism.

The Celtic-Ganderian orogeny

Subduction then switched to the SE margin of Iapetus (Fig. 3) and probably at this time also the Scandinavian arm of Iapetus was extended NE from Scotland as shown by Precambrian sedimentation in E Greenland through to N Norway. The trough sediments of the Mona and Cullinstown Groups were almost certainly laid down adjacent to, or upon, a continental crustal segment possibly of Archaean age. But they were also near oceanic crust as Anglesey contains most of the indicators of a subduction zone: greywackes intruded by a serpentinite-gabbro diapir, wildflysch, pillow lavas, cherts and basic rocks raised to blueschist facies. The upper part of the sequence contains acid

and intermediate volcanics indicating that in the later stages a volcanic arc supplied detritus to the trough area. To the south-east there was a widespread development of calc-alkaline volcanism and plutonism, all probably within the range 750-600 Myr, developed as a fairly typical cordilleran sequence on continental crust.

There seems to be no argument for a longstanding north-west dipping subduction zone since all the contemporary calc-alkaline volcanics lie to the south-east. It is more likely that a marginal basin developed between Anglesey and the Welsh Border and that a collision, closing this basin at ~600 Myr, caused the folding in Anglesey, and brought the blueschists and oceanic crustal slivers to the surface. The evolution of the belt in the English Midlands and Welsh borders follows the normal development of a cordilleran orogeny some way from a continental edge⁸.

In Newfoundland, Kennedy⁶ suggests that a Ganderian orogeny took place on this margin during the latest Precambrian, and advocates the same mechanism, although evidence for a marginal basin is lacking. The Cadomian¹¹ of Brittany and the Channel Isles has been more accurately dated than the rest of this area. It has been suggested²⁰ that Brioverian sediments developed on a south to south-eastward facing continental rise with possibly an ocean indicated by ophiolites in the south. This subsequently became deformed before 620 Myr by east-north-east folding and metamorphism which reached quite high grades in northern Brittany and culminated in the emplacement of late-orogenic intrusives as late as the Lower Cambrian¹¹.

The closely similar timing of the orogenic events of the Cadomian and the Celtic cycles suggest that they were in some way related but their relative positions at this time are unknown. It is possible that the relative positions of these two areas have been markedly altered during the Hercynian orogeny, although Ordovician fossil assemblages point to a single province in the whole of this area to the south-east of Iapetus²¹. On balance it seems most likely that the Brittany area was on a different continental margin. The late Precambrian of north-west Spain which has been compared with the Brioverian was not involved in any orogenic activity at this time²².

The climax of the Celtic orogeny resulted in the formation of a mountainous landmass on the south-east margin of

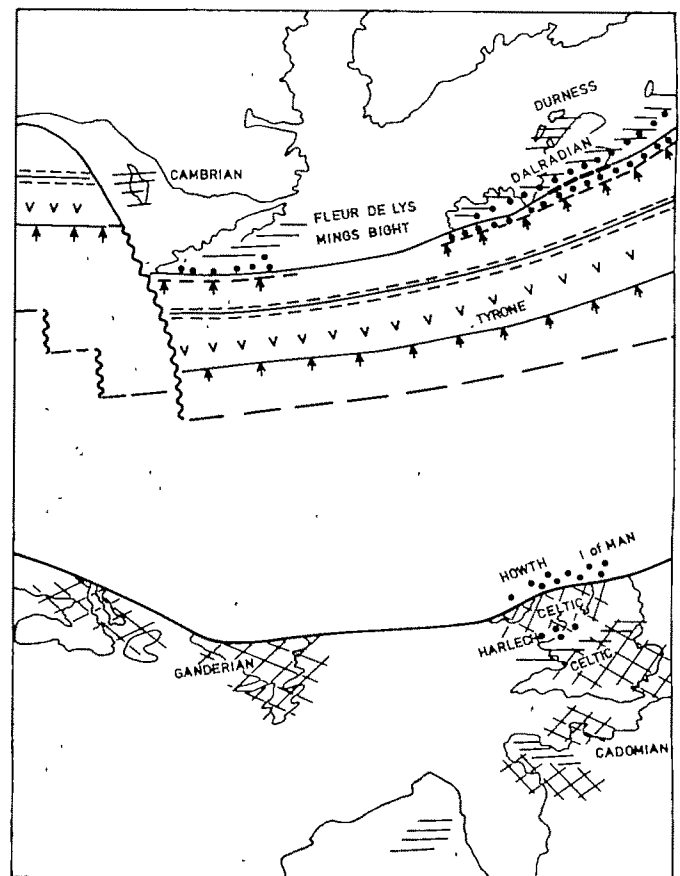

Iapetus and shortly after this there is evidence of increased activity on the north-west side of the ocean.

The Grampian-Burlingtonian orogeny

Following the formation of the Morarian mountains the north-west continental margin continued to receive trough sediments to the south-east of the Great Glen as the Central Highland Granulites (Fig. 4). These sediments show no earlier structural history than that affecting the Dalradian, so must be regarded as the lower part of that sedimentary sequence⁸. Similarly in western Mayo the Erris Group seems to be Moinian type sediment unaffected by any pre-Dalradian deformation¹⁸ and may again represent a post-Morarian early-Grampian trough.

Shelf sedimentation began in the lower Dalradian¹¹ and continued through Middle Dalradian (probably about the end of the Precambrian). All these sediments were being laid down, according to the present model, on the subsiding Morarian volcanic arc. From early Cambrian this shelf extended over on to the Torridonian beyond the Morarian chain, now largely eroded. In upper Dalradian (about Cambrian-Arenig), the continental margin began actively subsiding and great thicknesses of greywackes were deposited, probably marking the beginning of subduction to the north-west again. There are abundant basic volcanics (Tayvallich) in the upper Dalradian but they cannot represent slices of oceanic crust since they lie within a sequence of coarse, shallow-water quartzites. They could, however, mark the opening stage of a marginal basin. The intrusion of the Aberdeenshire layered gabbros (again, not a suture line) apparently after some of the early folding but before the climax of the orogeny indicates proximity to a source of abundant tholeiitic magma, and marginal basin activity would again seem a fairly logical source.

Fig. 4 Formation of Grampian and Burlingtonian. See Fig. 2 for key.

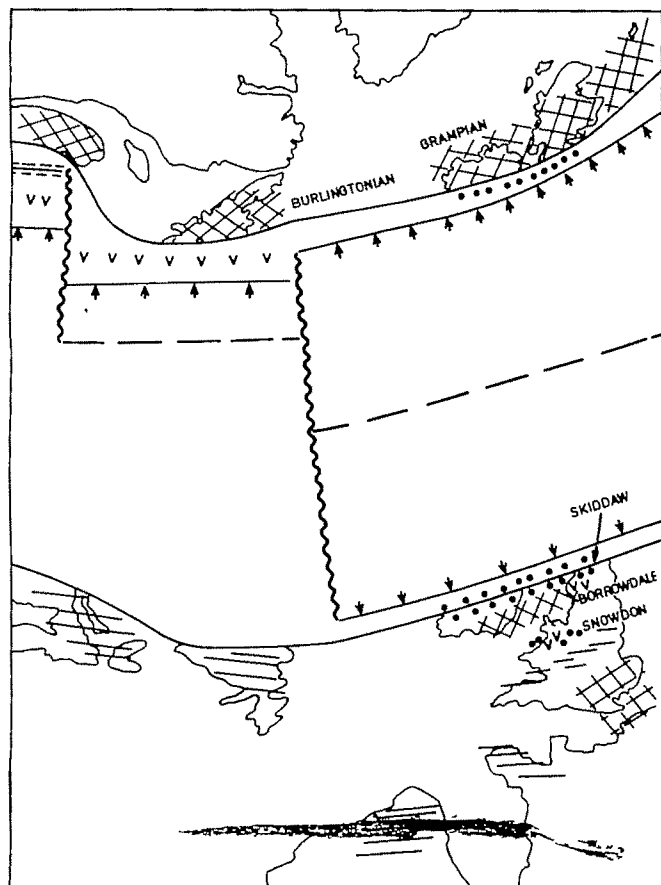

Fig. 5 Formation of Taconic, development of Lakelandian cordillera. See Fig. 2 for key.

The climax of the Grampian orogeny has not been precisely dated but must be about Arenig times. There was intense deformation accompanied by high temperature/high pressure metamorphism, so there is little doubt that it was a collision orogeny. A similar orogeny with clearer evidence of marginal basinal effects has been proposed⁶ for the Burlington peninsula of Newfoundland. This Burlington orogeny took place during the Tremadocian.

The necessity for a substantial collision to cause the Grampian orogeny without closing the whole Iapetus ocean, (and thus involving the Lake District and Wales in a major Arenigian deformation), necessitates the suggested development of an island arc to the south-east of the main part of the Dalradian. This would also explain the lack of calc-alkaline volcanics within the Dalradian sequence, or indeed of volcanics of Cambrian age anywhere in the British Caledonides. The abundant plutonic basic and acid intrusions in the Connemara Dalradian which were intruded at various times in the orogenic cycle could also be indicative of the proximity of that area to the major volcanic arc.

The cryptic suture which does exist along the Highland border (some Arenigian pillow lavas and serpentinite intrusions) probably thus only marks the line of closure of the marginal basin; the major continental fragment which may have had Cambrian calc-alkaline volcanic activity would now lie beneath and south-east of the Midland Valley. The recent LISPB experiment has shown that oceanic crust does not exist beneath either the Southern Uplands or the Midland Valley²³.

The Lakelandian and Taconic orogenies

Following the Grampian orogeny, subduction again switched to the south-east side with the development of middle-upper Ordovician volcanics and trough sediments in the Lake

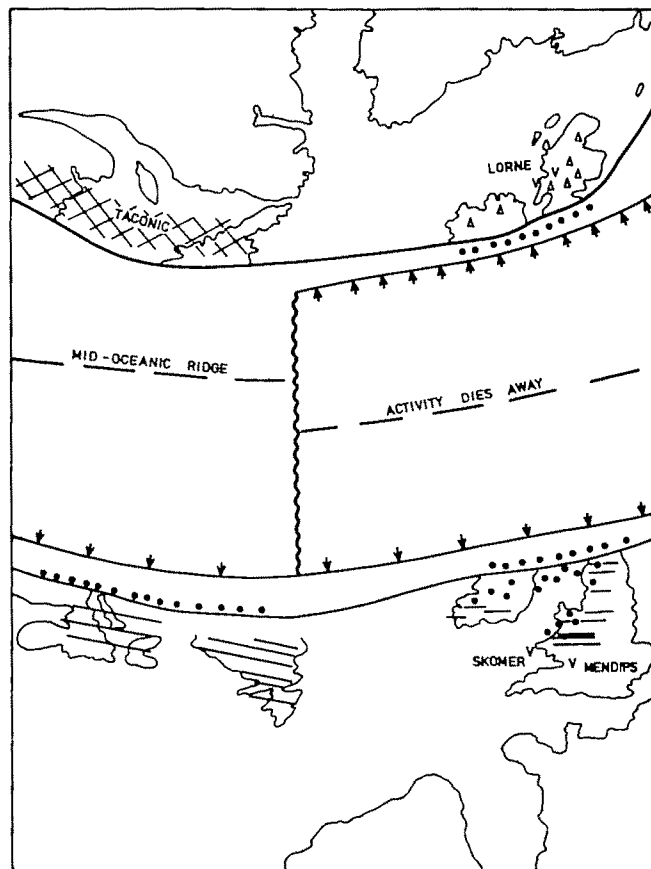

District and Wales (Fig. 5). This followed a period of basinal sedimentation between the Celtic trough area of Anglesey and the Celtic foreland of the Midlands which were both land areas for much of Cambrian and Ordovician times. Although black shales were at times being deposited, the mid-Welsh trough does not seem likely to have been a true oceanic area, but could represent an area of crustal thinning which never quite developed into a marginal basin (for example, the Llanvirn Head Pillow Lavas could mark the opening of such a basin).

There are pre-Borrowdale and pre-Bala earth movements which have been termed the Lakelandian¹⁹ and regarded by some as a major orogenic phase²⁴. It is, however, obviously not a major collision and must be regarded as a cordilleran orogeny on this side of the ocean which never developed a marginal basin or resulted in a major collision orogeny.

On the north-west side of Iapetus (south of the Scottish Highlands) subduction may never have ceased after the Grampian orogeny, since oceanic crust of Arenig to Llandoile age is preserved in the Girvan area²⁵ indicating either oceanic subduction or marginal basin activity in that area very shortly after the Grampian orogeny. In Newfoundland also, tectonic activity in Caradocian times emplaced large slivers of oceanic crust and mantle right over the Burlingtonian core⁶ and indicates that subduction to the north-west continued without much break after the Burlingtonian orogeny in the Newfoundland segment.

Further south-west in the Appalachians, the Taconic orogeny represents a major collision that does not correlate in timing or intensity with the Lakelandian. The age of the Taconic climax of activity is about Caradocian²⁶ and involves major thrusts and nappe type structures which, as with the Grampian, cannot be related to the Ordovician

Fig. 6 Closure of ocean. Formation of Caledonian and Acadian at final collision. Key as in Fig. 2.

history of the south-eastern side of Iapetus. This again implies that the two sides of the ocean were acting independently and the nature of the Taconic orogeny implies a major subduction and collision event in the south-western part of this belt during early and mid-Ordovician times on the north-western margin. It is perhaps most probable that the Burlingtonian orogeny did not take place there but was delayed until Caradocian times in the area south-west of Newfoundland.

The Caledonian orogeny

Whether subduction ceased to the south-east or not (volcanism continued to be active in Silurian times in the Mendips and South Wales), the calc-alkaline volcanism of Lorne and Glencoe suggest that active subduction was taking place beneath the Dalradian, with the subduction zone possibly in the Solway area²⁷ (Fig. 6). It may have been the effect of subduction to both north and south that allowed the closure of the Iapetus ocean, as by the middle of Silurian times the palaeontological evidence indicates that benthic fauna were in contact and by late Silurian or early Devonian the collision had taken place, marine sedimentation had ceased and the rocks of Wales, the Lake District, the Southern Uplands and Central Ireland became quite strongly folded. This is the first time that deformation at approximately the same time can be recognised occurring on both sides of Iapetus, another good indication that this was the first oceanic closure. Along the length of the orogenic belt the intensity of deformation associated with the major oceanic closure increases from Newfoundland (where it was mid-Devonian and very mild) to Scandinavia where it was much more intense than in Britain. In Scandinavia the Caledonian orogeny was so intense that Silurian rocks are metamorphosed and involved in major thrusting, so that the correlation of the orogenic events in that segment with the sequence proposed here has not been attempted.

This sequence of orogenic climatic events is thus envisaged not as a continuous orogenic cycle operating along a continental collision-site as many previous syntheses have portrayed the Caledonides, but as a discontinuous series of subduction/marginal basin formation/closure-collision events on either side of a long-standing major ocean which only finally closed in Silurian to mid-Devonian times and thus stopped any subduction or ocean spreading in this region. The model is clearly susceptible to testing by palaeomagnetic determination and may need revision in the light of local stratigraphic detail. The model does, however,

draw attention to one of the major features of plate tectonics applied to older palaeogeographic reconstructions that has not been too clearly recognised by many writers, namely the independence of events on one side of an ocean from contemporaneous events on the other. The correlations between the sedimentary history of the Mona complex with possibly contemporaneous sediments in the Dalradian or Brivoerian will be practically impossible, and largely irrelevant, if these three areas were on three different continental margins at different stages of activity or of different geotectonic type. Similarly, the search for the equivalents of the Taconic orogeny in southern Britain are irrelevant if the two areas were on margins of two different, independently acting, continents.

A major problem now apparent from the series of suggested events (Figs 2-6) is the reason for the closure of Iapetus and specifically why its mid-oceanic ridge stopped spreading. One must look again to a coupled series of events and the beginning of the Hercynian orogeny is closely related to the end of the Caledonian, so that it seems very likely that the starting of a major site of crustal extension and the formation of an ocean on the margins of which the Hercynian orogenies developed²⁸, was the cause of the failure of the Iapetus spreading centre and ultimately the closure of that ocean forever.

letters to nature

Oblateness of the atmosphere of Mars

ON April 8, 1976 Mars occulted the bright star α Geminorum (magnitude 3.2). Predictions¹ were issued well in advance since such occurrences are very rare: indeed, it is estimated that Mars occults a star as bright as this about once in 500 yr. Accurate observations of the duration of the occultation were made from four sites on the Earth and these are analysed here for the shape of the Martian atmosphere at that height at which the intensity of the starlight diminished by half. The oblateness is found to be about twice as great as that of the surface of Mars.

The occultation was widely observed throughout North America, the Caribbean area and Great Britain, mainly visually, although a number of photoelectric observations were also made. Of particular interest are the high accuracy photoelectric observations made from Greenbelt (Maryland), Atlanta (Georgia), Fort Davis (Texas) (G. de Vaucouleurs, et al., to be published) and from an aircraft over the western North Atlantic². Timed observations of '0.5 light' at the disappearance and reappearance phases of the occultation have been reported from these four places. The aircraft observations, from a height of > 12 km, were made at 4,500 Å—a shorter wavelength than that used by the ground

Fig. 1 Occultation of ϵ Geminorum by Mars on April 8, 1976 as seen by various stations. NP marks the North pole. Although the chords representing the photoelectric observations are nearly central, there is a good spread in latitude because of the tilt of the axis of Mars.

observers. Because of the very low altitude of Mars it was not possible to make photoelectric observations from the British Isles. This was unfortunate since a grazing occultation occurred from southern England, Wales and Ireland, and observations from localities such as these would have improved the coverage of the Martian disk considerably. This is clear from Fig. 1.

Using the known distance of Mars and its direction and angular rate of motion, it was possible to calculate the apparent positions of the star at the observed times, relative to the centre of Mars. A standard computer program, written by the author, for the analysis of previous occultations of stars by planets and satellites was used to solve for three unknowns—two for the position of Mars and one for the correction to the adopted equatorial radius. Several solutions were found using various trial values for the flattening of the Martian atmosphere, where the flattening is defined as [(equatorial radius—polar radius)/equatorial radius]. Calculations were also done without the aircraft observations since these were made at a shorter wavelength than the others and thus refer to a greater height in the Martian atmosphere. This did, indeed, prove to be the case, the height being ~ 6 km above the ellipsoid fitted to the other observations.

The position of the star was taken from the FK4 catalogue, while the ephemeris of Mars was obtained from the Jet Propulsion Laboratory. The analysis of the ground-based photoelectric observations showed that this ephemeris was extremely accurate. In fact, the derived correction to the ephemeris of Mars relative to the star was only

$$+0.0019 \pm 0.0001 \text{ s in right ascension (RA)} \\ +0''.009 \pm 0''.007 \text{ in declination (dec.)}$$

This correction is considerably less than the s.e. in the position of the star itself.

For the first solution the adopted value of the flattening was 0.0052, which is the dynamical flattening given for the surface of Mars by Lorell¹. By varying this value, however, it was quickly found that the s.e. of all three unknowns decreased as the flattening was increased and that the sums of the squares of the residuals went through a minimum when the flattening was ~ 0.012 – 0.014 . The results are

Table 1 Computer fits

Adopted flattening	Equatorial radius (km)	RA (s)	Correction to dec. (")
0.0052	$3,458.4 \pm 3.6$	$+0.00173 \pm 21$	$+0.0145 \pm 135$
0.0097	$3,461.6 \pm 2.3$	$+0.00185 \pm 13$	$+0.0115 \pm 87$
0.0135	$3,464.4 \pm 1.9$	$+0.00195 \pm 11$	$+0.0089 \pm 71$

given in Table 1. The residuals of the observations were very good—the greatest residual in the radius being 3.9 km, which corresponds to a timing residual of only 0.18 s.

The values for the equatorial radius have not been corrected for refraction. To obtain the true distance from the centre of Mars the scale height should be added. This is probably ~ 10 km, but will doubtless be determined more accurately from the individual light curves at a later date: it should then be possible to improve the solution by applying the scale height to each observation individually.

Table 2 Flattening and equatorial radii at various levels

Level	Flattening	Equatorial radius (km)	Method
Surface	0.0057 ± 0.002	$3,394 \pm 4.5$	Spacecraft radio occultation ⁴
?	0.0091 ± 0.002	$3,402 \pm 16$	Visual micrometer observations ⁵
0.5 light	0.013	$3,474 \pm 3^*$	Photoelectric occultation

*Includes an estimated error for the scale height.

Table 2 shows the flattening and equatorial radii at various levels. For comparison purposes the radius derived from the photoelectric observations has been increased by an assumed scale height of 10 km.

It may eventually be possible to express scale height as a function of latitude. Since the observations at each phase range over only 25° in latitude, however, it is unlikely that there will be a marked change in the flattening.

The cause of this observed flattening may partly arise from a diurnal variation in density—the disappearance phase occurred on the unilluminated limb while the reappearance phase occurred on the illuminated limb. No such effect, was, however, detected when Jupiter occulted a star in 1971, the flattening at 0.5 light level being very close to the dynamical flattening⁶.

In conclusion, it would seem from this analysis that the 0.5 light level has an equatorial radius of $3,464 \pm 2$ km (+ scale height) and a flattening in the range 0.012 to 0.014.

Hydrodynamics and geodynamics in the Phlegraean fields area of Italy

WE show here, from an analysis of geological observations in the Phlegraean Fields, that the high correlation among slow ground motions, seismicity and short and long period tidal components (including the Chandler wobble) observed at Pozzuoli (Naples) suggests that the sea, throughout intercrustal

hydrodynamic correlation, may be an important geodynamic agent.

The intense Phlegraean–Vesuvian volcanic event occurred in Campania (southern Italy) in the area lying between Monte Massico, the margins of the pre-Apennine arc, the Sorrento peninsula and the Gulfs of Naples and Pozzuoli¹. The Phlegraean Fields are the volcanic district W of Naples (Fig. 1a), some of whose craters form part of the city's urban system. The Phlegraean volcanic activity, as opposed to that of Vesuvius which is famous for its lava manifestations, is mainly characterised by huge explosions of the phreatic type, with ejection of predominantly ash products. A thick buildup of which is followed by intense diagenesis with the formation of the classic Phlegraean lithoid tuffs. The characteristics of these tuffs are their considerable cohesion and very high porosity (40% at the surface); consequently their rheological behaviour can be compared with that of a sponge dipped in water².

The morphology of the Phlegraean Fields is characterised by shallow craters sometimes affected by marine erosion, by many thermal springs both on land and under water, some feeding the

Fig. 1 Phlegraean Fields volcanic basin. a, First-order residual gravity anomalies. Also shown: survey points; morphological and structural borders of the caldera; the west-east and north-south trends of the profiles of Fig. 1b and Fig. 4 respectively. b, Profiles of the maximum uplift (—▲—▲—) and residual gravity anomalies (—), with the geological cross section according to the west-east trend.

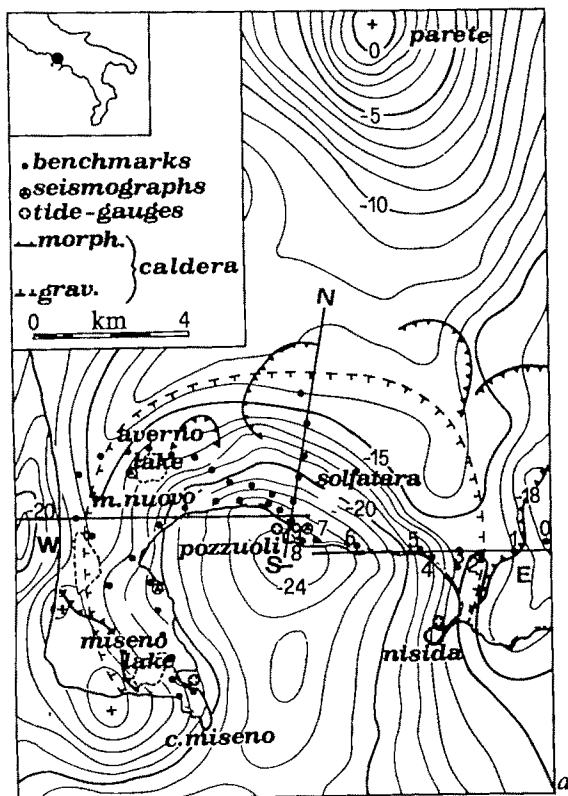

Fig. 2 Trend of Phlegraean bradyseism over the centuries. (—) Parascandola's trend; (— · — · —) represents the modified curve. ↑ gives date of historical uplift; *, a major eruption in Campania; ◆, a major earthquake in Campania; ●, a major earthquake in Campania, also causing damage in Naples; ▼, an earthquake in Pozzuoli.

spas that were already famous in Roman times, and by solfatara fields. The dynamics of the Phlegraean Fields is characterised by a vertical movement of the crust to which has been attributed the Greek term 'bradyseism'. The latter brought about one of the longest series of continuous up-and-down movements. In fact, the trend of this local vertical movement, that has continued for many centuries at a time, has been reconstructed from the study of the clear traces left by the lithodomes on the surface of the columns of the Roman *Mercatum*, called Serapeo, built in the second century BC at Pozzuoli.

Figure 2 shows the diagram drawn, as an unbroken line, by Parascandola³, which is also based on the data collected by Nicolini⁴ in the middle of the nineteenth century. It is particularly interesting to note that in 1538 there was a ground uplift of ~ 7 m in only 48 h when the eruption of Monte Nuovo took place, and that the maximum uplift was recorded in Pozzuoli at ~ 3 km from the point of eruption.

In the study of the origin of Phlegraean bradyseism⁵ the lowering phenomenon is interpreted as being a result of compaction through overloading of the light pyroclastic products filling the Phlegraean basin down to a depth of 3.5 km (gravimetric model shown in Fig. 1b).

The uplift, on the other hand, is interpreted as being the result of the rheological behaviour of the porous fluid-saturated media affected by the flow variation in these same fluids as a consequence of both a variation in the amount of heat carried up from below (increase in the convective movements) and the seismoeruptive effects of the phreatic explosion.

Moreover, as it is well known that earthquakes are also accompanied by ground uplift events, which, although much smaller than those recorded for the Phlegraean area, have similar characteristics, Parascandola's diagram has been suitably modified as shown in Fig. 2 with the dash and dot line.

The proposal to modify the trend of the historical data was made on the assumption that when the local and regional eruptions and earthquakes take place there may also be discontinuity, with a rapid ground uplift and a successive return to subsidence conditions. Only the eruptions of Vesuvius of the years AD 79 and 1631 have been considered, as they began new eruptive cycles after a few centuries of inaction.

The hypothesis that the Phlegraean uplift movements take place over short periods of time is confirmed by the recent inversion of bradyseism noted in early February 1970, whose development is shown in Fig. 2.

The recent event, which probably began in 1969 and continued for four years, has enabled the study of some of the characteristic manifestations.

The inversion was seen to be accompanied by a continual increase in steam flow from the fumaroles and a widening of

Solfatara di Pozzuoli mud pool. The increase and decrease of these reflected the ground uplift trend. No variation in the temperature of these same manifestations was ever observed.

The data we have analysed were gathered by several companies and organisations⁶ and covered the following: ground movement, microseismicity and sea movement.

In the case of the ground uplift that took place from March 1970 to February 1973 the Campanian Public Works Office carried out precision level measurements on several tens of benchmarks throughout the Phlegraean zone. The heights had been checked various times between 1903 and 1953. Along the Naples (Fuorigrotta)–Pozzuoli coastline the measurements made on benchmarks numbers 0–9 were made on average at monthly intervals. The resulting uplift data were found to have both area (Fig. 1b) and time dependencies (Fig. 3). Figure 3a shows that the ground movement trends with respect to the maximum height reached in the individual benchmarks are in close agreement with one another.

The maximum uplift was reached in July 1972 (Fig. 3) and the average trend for benchmark 7 (where the absolute maximum was reached) can be expressed by a typical diffusion equation

$$q = q_0 + m \exp[-\lambda_1(t_0 + t)] - n \exp[-\lambda_2(t_0 + t)]$$

where q is the height reached, m , n , λ_1 and λ_2 are constants

Fig. 3 Time dependence of the ground uplift in the Phlegraean Fields. *a*, Variation (with respect to March 9, 1970) in the height of the benchmarks assuming for each one the height reached on July 6, 1972 (referred to as q_m in the figure) to be 1.0. Benchmark 0 is regarded as being stable. This shows the average value for each series of measurements and the interval (I) containing the random distribution of the single values from the 9 benchmarks. For benchmark 0, q_m was 0 (cm); for 1, 3.00 cm; for 2, 8.5; for 3, 17.36; for 4, 28.75; for 5, 35.89; for 6, 69.51; for 7, 70.37; for 8, 68.46; for 9, 64.60. *b*, High accuracy levelling values for benchmark 7. Ordinates (origin at the level of May 19, 1969) are the lower set on the left and go on near the curve. *c*, Best fit curve (see text); *d*, *e*, *f*, trends obtained from tidal data given in Corrado and Palumbo⁶. Ordinates are on the right (the origin is not at the same level as the *b* and *c* curves).

Fig. 4 Trend of uplift from 1962 to 1970 and (n-1) the order gravimetric residual anomalies; topographic profile and geological cross-section along the N-S profile indicated in Fig. 1a (after Montagna⁷).

chosen to give the best fit to the experimental data; t_0 is when the bradyseism inversion began (\sim May 19, 1969; $t_0 = 285$ d) when $q = -23.77$ cm, compared with the height measured in 1953 by I.G.M. This is in agreement with the dependence of uplift on the variation of the flow of fluid within porous layers (Fig. 3c).

The uplift profile (Fig. 1b) shows an increase from the borders of the caldera inwards, that is, from almost negligible values to 156 cm compared with the height in 1953 (180 cm compared with May 1969 when the inversion of the phenomenon probably began). The uplift values can be connected with different thicknesses of the pyroclastic layer (Fig. 1b).

During the recent uplift, the altimetric survey made by the Italian Geological Survey in 1962 (ref. 6) along the N-S profile of Fig. 1a was repeated (April 1970) and a more detailed gravimetric survey⁷ was also carried out. The two-dimensional model, drawn from the first-order residual anomalies, compared with the height variations, shows a clear correlation between the type of uplift and the thickness of the pyroclastic products covering the limestone substratum. Figure 4 reveals the correspondence between the uplift discontinuities and the position of the faults⁷.

These observations are in agreement with the data on the ground movement obtained⁸ by comparing the average sea level far away (the Naples and Pozzuoli tide-gauging stations).

The correlation coefficient between the data in Fig. 3b and those in Fig. 3d was found, by Pearson's formula of the product moment, to be 0.994.

The curves shown in Figs 3 and 5c reveal that the uplift in the different stations in the Phlegraean Fields between 1970 and 1975 has a trend which is the combination of different periodical components.

Three seismic stations have been in operation⁸ since March 1970 to study the seismicity in the Phlegraean Fields. At the Pozzuoli station (Vescovado: Fig. 1a), where the majority of the seisms have been recorded, 5,752 seismic events were noted up to February 1974. The foci were essentially concentrated within a depth of 3.5 km and had a random distribution.

Fig. 5 Trend of seismicity, vertical ground movement and sea movement at Pozzuoli. *a*, Number of daily seismic events recorded at Vescovado station; *b*, Average daily sea level; *c*, Ground uplift calculated by subtracting the average trend values from those of the curve in Fig. 3*d*; *d*, average daily number of seismic events for 29 consecutive days along with the relative average trend; *e*, analogous values and average curve for the tide amplitude; *f*, average daily seisms in function of the Moon's age for the period 1970-74; *g*, average 10-d seisms for the same period

Only about ten of these were felt by the local population, having reached an intensity of III-IV Mercalli degrees.

Also the daily trend of the seisms is clearly periodical (Fig. 5*a* and 5*d*): the long period trend is accompanied by several short period trends, in particular the fortnightly (Fig. 5*f*) and six-monthly (Fig. 5*g*).

The average daily sea level (Fig. 5*b*) and the sea-level variation over 6 h (an index of its mean velocity), obtained by subtracting the low tide level from the previous high tide level (Fig. 5*e*), refer to Pozzuoli station (Capitaneria di Porto). The latter curve also shows, besides the smaller period trends, a clear long period one.

The correlation coefficient of the average curve drawn from Fig. 5*d* and *e* is 0.81, also calculated from Pearson's formula: the 99% confidence limits are 0.69 and 0.89.

This suggests that there is a direct connection between the sea motion, considered as a 'tidal pumping', and the micro-fracturing of the skeleton of the highly porous and permeable pyroclastic layer.

The trend of the uplift curve (Fig. 5*c*), obtained at Pozzuoli by subtracting the average uplift values from the values of the curve in Fig. 3*d*, is analogous to those of Fig. 5*d* (daily seismic events) and 5*e* (tide amplitude) and the correlation coefficient, as calculated once again from Pearson's formula, between values in Fig. 5*c* and *d* is -0.73: the 99% confidence limits are -0.84 and -0.57.

In spite of the short interval considered (1,400 d) the fact that the three phenomena have a common period of 400-450 d brings to mind the Chandler wobble. To confirm this connection the analysis of tidal and geodynamic (earthquake and vertical ground movement) data should cover a period of at least 7 yr.

In conclusion, it would seem that the phenomena accompanying the Phlegraean bradyseism give support to the interpretation of its genesis² based on the alteration of intercrustal

hydrodynamics, and in particular they suggest that the sea has an influence on local geodynamics.

Ophiolite emplacement on to continental margins

RECENT work on west Newfoundland ophiolites supports Elliott's¹ contention that the mechanics of emplacement of oceanic crust and upper mantle on to continental margins ('obduction') is no different from the emplacement of thrust sheets in any foreland thrust belt. Evidence to this effect comes from the presence of minor structures found along the thrust fault surfaces separating the various structural slices, as well as from other related minor structures—hitherto unrecorded in ophiolite suites—that have been found within the thrust sheets themselves. These

reveal a very specific kind of information about the mechanics of ophiolite transportation and, without reference to the forces causing emplacement, they imply that many of the processes involved in the motion of ophiolite thrust sheets are equivalent to those typical of foreland thrust belts—due consideration being given to basic differences in the material properties of the rocks involved.

As far as the basal metamorphic aureole associated with the western Newfoundland ophiolites is concerned, it is clear that it predates their transportation on to the continental margin. Direct evidence to this effect is found in the Bay of Islands complex² where the low greenschist grade thrust faults that are responsible for ophiolite transportation obviously truncate the higher grade aureole, placing it and the adjacent ophiolite stratigraphy structurally over and above the unmetamorphosed oceanic sedimentary rocks. In other places this low greenschist grade structural base may follow the pre-existing metamorphic aureole³, using it as a suitable discontinuity, analogous to a bedding plane thrust in a foreland thrust belt; although this would appear to obscure the history and chronology of the two events (that is, an earlier one that produced the higher grade metamorphic aureole, from a later one that emplaced the ophiolites on to the continental margin along greenschist grade thrust faults), a distinction can be made on the basis of minor structures observed within the thrust sheets themselves. These take the form of narrow ductile deformation zones (DDZ, see Fig. 1) formed during the motion of the ophiolite sheet; locally these clearly truncate and retrograde to greenschist facies the granulites and amphibolites of the basal aureole, as well as parts of the overlying ophiolite stratigraphy. Such relations express, rather explicitly, the lack of significance of the basal metamorphic aureole in terms of the immediate processes inherent to the orogenic belt in which the ophiolites have been emplaced. In terms of its pre-emplacement significance, one wonders if the high temperature aureole might be explained as the product of dynamic conditions induced during seafloor spreading, by the lateral flowage of oceanic crust and upper mantle in the vicinity of an ocean ridge? Or, could it be the vestige of a subduction zone fabric?

With respect to greenschist grade emplacement mechanics, the presence of narrow ductile deformation zones throughout a large volume of an ophiolite thrust sheet shows that there is a fundamental difference in the internal energy dissipation⁴ within an ophiolite thrust sheet, compared to that of a foreland thrust sheet involving only unmetamorphosed cover rocks. In the latter, a large proportion of energy is absorbed by folding, generally taking advantage of the facilitating slip planes provided by well developed bedding. In contrast, in the massive or crudely layered crystalline rocks which constitute most of an ophiolite sheet, deformation is much less homogeneous, taking place along narrow, often distantly spaced, ductile deformation zones. Their number and intensity varies according to position within the ophiolite thrust sheet; although no attempt has yet been made to quantitatively evaluate this, clearly they are much more widely spaced and weakly developed throughout the bulk volume of the thrust sheet than near its base. In the proximity of the fault plane (within 30 m) there is a seemingly exponential increase in the number of DDZ; at the fault, the deformation zones run together, with small ones feeding larger ones—in effect, emptying their displacement cumulatively into large shear zones which subsequently empty theirs into the main thrust fault at the base of the ophiolite slice. Similar ductile deformation zones have been described by Ramsay and Graham⁵, and Mitra (unpublished) in deformed crystalline basement and intrusive rocks of several orogenic belts. Their significance here, in terms of ophiolites, lies in their recognition for the first

Fig. 1 *a*, Asymmetric ductile deformation zone cutting across the gabbro cumulates, east side of Blow Me Down Mountain, Bay of Islands complex. *b*, Close-up of a sample from the same deformation zone, showing the spectacular grain-size reduction of the original mineralogy (coarse pyroxenes in feldspar matrix) to a narrow, greenschist-grade mylonite.

time as diagnostic minor features related to the transportation and emplacement of oceanic crust and mantle on to a continental margin. Although in terms of internal energy dissipation they record a fundamental difference between ophiolite and foreland thrusts, this is only important in consideration of the material properties inherent to the specific thrust sheet.

Information on the physical mechanisms operative at the base of a moving ophiolite thrust has been recorded by a variety of minor structures along the actual fault surface. These include: (1) fibrous accretion steps (micro-lite fibres where ultramafics occur in the hanging wall), and (2) striations, gouge, and polished surfaces, similar to those features described by Elliott. These are indicative of pressure solution slip and frictional sliding processes operating at the base of a moving ophiolite sheet, as in the case of a foreland thrust⁴.

This work was supported in part by a grant from the Geological Society of America, as well as by a scholarship from NRC of Canada.

Water movement in porous media towards an ice front

IN frozen soils water movement towards an ice front can occur, leading to the formation of ice lenses, frost heaving and damage to roads and other structures. During the past decades many attempts have been made to explain the transport phenomena involved, fundamental contributions being made by Everett¹ and Takagi², among others. We present here experimental results on the influence of pressure on ice growth; they accord with thermodynamic theory.

At our laboratory Vignes and Dijkema³ studied the flow of water towards an ice front through a very narrow slit ($50\text{ nm} \times 1\text{ mm} \times 50\text{ mm}$), all walls consisting of quartz. They found that under isothermal conditions the flow occurred at a rate proportional to the degree of subcooling. This result was confirmed at our laboratory by De Loos (internal report) who studied flow of water towards an ice front through a glass cylinder of 1 mm^2 cross section, containing 10^4 parallel cylindrical capillary channels of $1\text{ }\mu\text{m}$ diameter.

Fig. 1 Ice column (diameter $\approx 7\text{ mm}$) formed during 15 d after starting ice growth. $T = -0.045^\circ\text{C}$, $p_i = p_w = 101\text{ kPa}$.

Vignes and Dijkema³ explained their experimental results by suggesting that the seat of the phenomenon is to be found in the thin layer of unfrozen adsorbed water between the ice and the quartz wall. The pressure distribution in this layer is thought to be anisotropic, leading to heaving of the ice by the disjoining pressure on the one hand, and water flow by suction in a direction parallel to the wall on the other hand. This was

elaborated on by Vignes⁴ in a theoretical study, treating the thin water layer as a micropolar fluid.

In subsequent experiments we extended this work by investigating the influence of pressure on the rate of water movement. Ice and super-cooled water were separated by a horizontal glass filter, all walls consisting of glass as well. The ice was situated on top of the filter. The pressure of the water and the ice could be controlled independently.

Under isothermal conditions, and at atmospheric pressure on both ice and water, water flow towards the ice was again observed. Figure 1 shows an ice column formed during 15 d of stationary conditions.

Fig. 2 Photograph taken at condition of no water flow. $T = -0.05^\circ\text{C}$, $p_i - p_w = 63\text{ kPa}$, $p_i = 101\text{ kPa}$.

Decreasing the water pressure at constant temperature, while the pressure on the ice remained at 1 atm, led to a decrease of the rate of water movement and eventually to a reversal of its direction, accompanied by melting of the ice. This is illustrated in Figs 2 and 3; it can be clearly seen that the ice column melts at the bottom.

The pressure difference between ice and water at equilibrium (no water flow) is found to obey closely the equation

$$p_i - p_w = -h(T - T_0)/v_w T_0$$

where the subscripts i and w refer to ice and water, p is pressure, T temperature, T_0 equilibrium temperature at $p_i = p_w = 1\text{ atm}$, h specific enthalpy of fusion, and v specific volume. This equation can easily be found by equating the differentials of the chemical potentials of ice and water and the subsequent

Fig. 3 Photograph taken 1 d after that of Fig. 2. $T = -0.05^\circ\text{C}$, $p_1 - p_w = 76\text{ kPa}$, $p_1 = 101\text{ kPa}$.

integration for constant h and v_w . The temperature range investigated was -0.01°C to -0.06°C .

Inaccuracy in rainfall measurement

RAINGAUGES are intended to give accurate measurements of precipitation. There is, however, a growing interest in the chemical composition of rainwater, and in the effects of chemicals in rain on plants and soil. It is also sometimes realised that the water collected in raingauges may be contaminated by dry deposition on the collecting funnels, and also by chemicals derived from the materials used in constructing these funnels and the collecting bottles beneath them.

For this latter reason, raingauges may be constructed of high density polythene, or of polypropylene, materials found not to contaminate seriously the water they collect. The collecting funnels of these raingauges may be cleaned at various intervals by different workers, in an attempt to reduce surface contamination. Unless the cleaning is done in a standard way at a standard time, the chemical analyses of different samples may be difficult to compare. It is fairly

common practice to clean funnels once a week, when samples are being taken. This may mean that in dry weather all surface contamination is lost, while if it rains just before the surface is cleaned much of the soluble material on the funnel's surface will be washed into the collecting bottle.

I now find that cleaning the polypropylene funnels may also affect the volume of the samples of rain collected. Funnels which have been exposed for several months, and which have been washed only by the falling rain, allow all the precipitation falling on them to run quickly down into the collecting bottles. The same happens with dew. These 'dirty' funnels measure the rainfall accurately.

When, however, the funnels are cleaned by daily wiping with paper tissue damped with distilled water, they behave quite differently. Their surface is seen to be covered with beads of water immediately after rain, or in the early morning when there has been a heavy dew fall. This water does not run down into the collecting bottle, and is rapidly evaporated and lost when the weather is dry.

The amount of water lost may not be insignificant. The polypropylene funnels I use have a diameter of 20 cm. This means that they collect 31.4 ml of water for each mm of rainfall. Shortly after an occasion where there was a rainfall of 0.8 mm, the 'dirty' funnels were almost completely dry, having transferred 25 ml of water to their collecting bottles. The 'clean' funnels were covered with drops of water. These were mopped up with paper tissues, which were then weighed. The water on the funnels was found to amount to between 5 and 6 ml. With this slight amount of rain the shortfall in collection amounted to some 20%. In heavy rain the loss is not, proportionately, so great, but it is still significant.

This behaviour of the raingauge surface will not only affect the volume of water collected; it will also affect the way in which the surface deposition is dissolved. A heavy dew or a slight shower which runs off the 'dirty' funnel will remove much soluble deposition, while on a 'clean' funnel, if the dew or rain is not collected, any salts dissolved will be redeposited when the water evaporates, and they will not appear in the sample which is collected and analysed.

It thus seems that, if we are interested only in accurate measurements of the amount of rainfall, we should not clean the surfaces of our collecting funnels. If we are interested in rainwater chemistry, we should plan our work knowing that the results may be affected by the treatment given to the collecting surfaces.

Gas velocities inside a burning cigarette

To understand more fully the factors that contribute to the formation and mass transfer of products within a burning cigarette, and to specify the type of reactions occurring, it is necessary to know the velocity of gases inside the combustion coal. In this study, velocities have been calculated from pressure and temperature distributions inside the burning cigarette. Gas velocities as high as 400 cm s^{-1} occur within the coal during a puff. Thus the residence times of gases in the coal can be much lower than 1 ms. This time is not long enough to allow molecular reactions of primary products in the gas phase to contribute to the final products.

The direction of the flow of gases inside the cigarette can be obtained from the internal pressure distribution, since the gas flow is perpendicular to the pressure contours and is towards

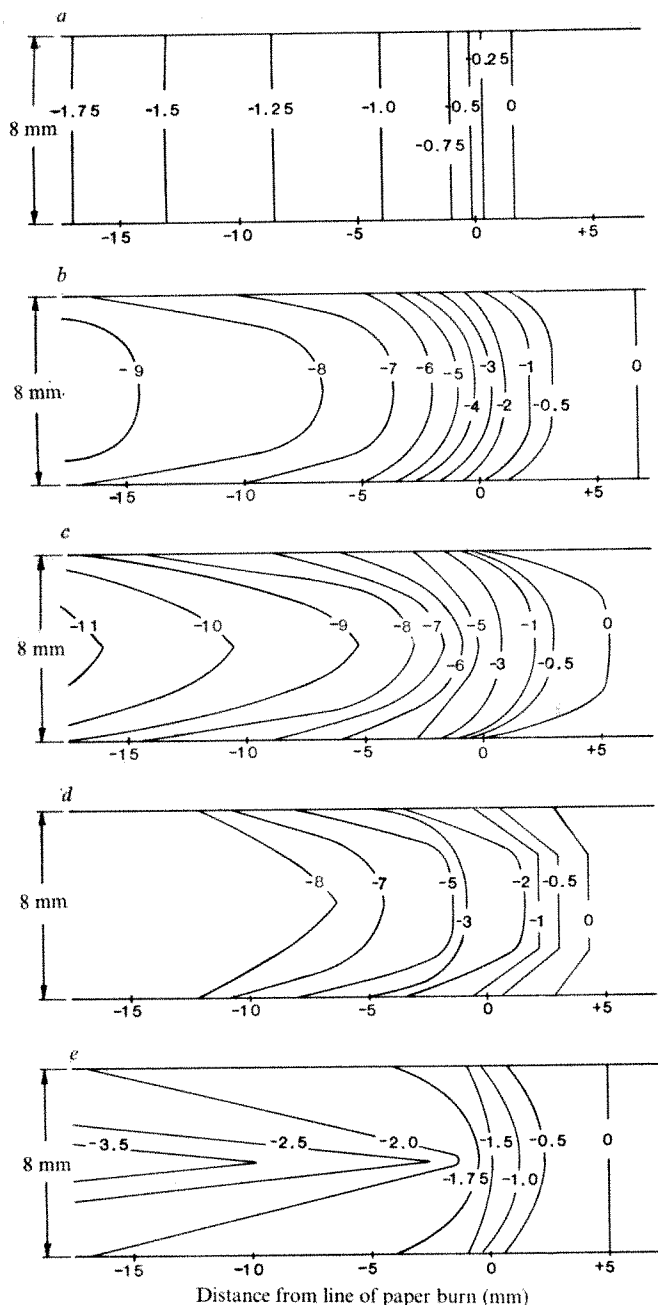

Fig. 1 Pressure (cm water) distribution in the cigarette at various times after the start of a 2-s, 35 cm³ puff (with a square pressure-time puff profile). Axial positions in the unburnt tobacco rod are quoted as negative distances from the burn line, while positions in the coal and ash are quoted as positive distances. *a*, 0.1 s; *b*, 0.5 s; *c*, 1.0 s; *d*, 2.0 s; *e*, 2.1 s.

lower pressures. Furthermore, inside a cigarette the volumetric flow of gases (V , cm³ s⁻¹) and pressure differential (ΔP , cm water) across a given length (L , cm) obey Darcy's Law¹

$$V = -\frac{1}{\epsilon} A \frac{\Delta P}{L} \quad (1)$$

where A is the area through which the gas flows (cm²), ϵ is the impedance of the tobacco bed at room temperature (cm water s cm⁻²), and 1 cm water = 98 N m⁻².

The impedance of a body is directly proportional to the viscosity (η , poise) of the fluid flowing through the body². A previous study has confirmed that the structure of the tobacco bed does not change significantly with temperature¹, so that ϵ is a function of η only. Consequently, if the flowing gas is at

temperature T , from equation (1) the component of velocity u_x (cm s⁻¹) in any direction is given by

$$u_x = -\frac{1}{\epsilon} \frac{\eta_0}{\eta_T} \frac{\partial P}{\partial x} \quad (2)$$

where η_0 and η_T are the viscosities of the gas at room temperature and T , respectively.

Thus, since the temperature distribution of the gas phase inside a burning cigarette is known³, the gas velocities inside the cigarette can be obtained from the pressure distribution using equation (2), assuming that the viscosity of the gases inside the cigarette vary with temperature as does air. This assumption is not critical, since the major gas phase components inside the cigarette (nitrogen, water, carbon monoxide, carbon dioxide and oxygen) all have viscosities whose variation with temperature closely parallels that of air^{4,5}.

The pressure distribution inside the cigarette during the third puff of the smoking cycle has been determined. A quartz glass tube, 0.80 mm internal diameter, 1.12 mm outer diameter, and 35 mm long, was inserted radially into the cigarette, while its other end was connected to an Ether type UP1 pressure transducer. The output from the pressure transducer was monitored on a CAMAC data logger. The resolution of a pressure measurement was ± 0.01 cm water. The transducer-probe system gave 100% response to a pressure change from ± 10 cm water (relative to atmospheric pressure) to atmospheric pressure in under 0.1 s.

The cigarettes used, and the experimental and computational techniques, were similar to those described previously for determining the temperature distributions³.

The pressure contour distributions during the puff are shown in Fig. 1. The mean pressures have 95% confidence limits of up to 25% of their value, due to slight variations in the cigarettes used. Consequently, the quoted pressure distributions are very much mean distributions, and the distribution in an individual cigarette could be significantly different.

The mean pressure contours 0.1 s after the start of the puff are all perpendicular to the cigarette axis (Fig. 1*a*). Thus, the

Fig. 2 Gas velocity (u_x , cm s⁻¹) along the central axis of the cigarette at *a*, 0.5 s; and *b*, 1.0 s after the start of a 2-s puff. The cigarettes had an impedance of 0.042 cm water s cm⁻².

gas flow through the cigarette is entirely parallel to the cigarette axis. Furthermore, the flow only extends to a distance of 1.5 mm in front of the line of paper burn.

At 0.5 s after the start of the puff, the pressure within the cigarette decreases further, air leakage through the paper causes convex shaped contours behind the coal, measurable negative pressures extend for up to 6.6 mm in front of the paper burn line, and the pressure contours in the coal are convex (Fig. 1b). Consequently, at this time in the puff, a proportion of the air enters the coal in an approximately radial direction, just in front of the paper burn line. As the puff progresses (Fig. 1), the pressure contours in the vicinity of the paper burn line tend to become more nearly parallel to the

Fig. 3 Gas velocity (u , cm s⁻¹), d mm from the paper burn line, along a line at 45° to the central axis, at various times during a 2-s puff: a, 0.5 s; b, 1.0 s; c, 1.5 s; d, 2.0 s.

cigarette axis, indicating that the air influx in this region becomes more nearly radial. Thus, during a puff, air initially enters the coal in a radial direction in the vicinity of the paper burn line, and its line of flow gradually becomes axial behind the coal. Consequently, it is largely the peripheral region of the coal that burns during a puff, as has previously been observed by direct studies⁶.

The pressure distribution 0.1 s after the end of the puff is shown in Fig. 1e. The pressures inside the cigarette have increased considerably (become less negative) in the ensuing 0.1 s, particularly at the peripheral regions of the cigarette behind the paper burn line. Thus, when the puff ends, air must enter the cigarette predominantly through the paper. Within 1 s of the puff ending, no mean negative pressures are observed within the cigarette.

The gas velocities along the central axis of the cigarette during a puff, calculated using equation (2) and data from Fig. 1 and ref. 3, are shown in Fig. 2. At distances greater than 20 mm behind the line of paper burn, where the flowing gases are close to room temperature, the linear gas velocity along the central axis is 30–42 cm s⁻¹ at all times during the puff. The greatest linear velocities along the central axis (160–250 cm s⁻¹) are obtained just in front of the line of paper burn (Fig. 2).

Gas velocities in any direction of interest can be calculated. Inspection of Fig. 1 suggests that a major route for gas intake into the coal throughout the puff is at an angle of 45° to the central axis, and intersecting the paper at the burn line. Calculated velocities along this line are given in Fig. 3, and it is seen that 1.0 s after the start of the puff, gas velocities in excess of 400 cm s⁻¹ are obtained. Along this line, 1.0 s after the start of a puff, the gas temperature falls from 520 °C at the burn line to 100 °C 1.4 mm away³. Consequently, the incoming gases have been heated to 520 °C, and then cooled to 100 °C, in 350 μ s. Molecular reactions of intermediate volatile products are almost certainly too slow to occur in the residence times available in the hot coal. This means that further reaction of primary decomposition and combustion products in the gas phase must occur by radical reactions and possibly by ionic reactions as well.

It is interesting to note in Figs 1 and 2 that measurable pressures and central axis gas velocities only extend to distances of about 5 mm in front of the paper burn line during the puff. Hot gases (temperatures greater than 100 °C), however, extend to distances of 11–13 mm in front of the paper burn line³. Consequently, diffusion processes, and not forced flow processes, are the major mechanism by which the mass transport of gases occurs in the coal at distances greater than about 6 mm from the paper burn line.

I thank Mr B. G. Bunn, Mr J. M. Davey, and Dr K. D. Kilburn.

Dependence of induced mutation on spontaneous mutation in *Tribolium castaneum*

In plants the effect of physical and chemical mutagens has been found to depend on the frequency of spontaneous mutation^{1,2}, but no such information is available from animal material. I have therefore investigated the relationship between spontaneous and X-ray-induced somatic mutation in the flour beetle *Tribolium castaneum*. This relationship was found to be positive and significant when the genotype was manipulated by artificial selection for speed of development.

The criterion used consisted of the wing developmental abnormalities that are under genetic control (21 genes have been identified, all with a recessive mode of inheritance³) and are subject to environmental modification^{3–5}. The data are the same as those for the lines selected for speed of

development⁴. Beetles were irradiated as 1-d-old pupae with 10 kR and the induced somatic mutations were observed in the adults which emerged. Spontaneous mutations were observed in non-irradiated samples. The experimental conditions were maintained at 33 °C and 70% relative humidity.

Figure 1 shows that the rate of induced mutation was dependent on that of spontaneous mutation among wild, slow and fast lines of beetles. The degree of determination of R^2 is very high (0.994), indicating that variation in the induced mutations could be explained by variation in their spontaneous rates.

Because the rate of mutation for wing abnormalities is under genetic control and is subject to natural and artificial selection^{5,6}, both types of mutation could be an expression of common underlying processes in the enzymatic system acting on the regulatory mechanism which controls DNA synthesis and repair⁷. The slow line is expected to have the lowest rate of both spontaneous and induced mutation, for slowing of development gives more time for repair to take place⁴. The wild type, the best fit genotype, has higher mutation rates than both the selected strains. These results confirm that the optimal mutation rate within wild strains is favoured by natural selection⁸ and is independent of the rate of lethal mutation, as a high mutation rate is expected to have deleterious effects⁹. On the other hand, the relationship between fitness (% adult emergence) and mutation rate (% wing abnormalities) for eight wild strains of *T. castaneum* was negative¹⁰ ($r = -0.82$, $P < 0.05$).

A line selected for intermediate development values (stabilising selection) showed a higher degree of spontaneous mutation and a slower degree of induced mutation than did

Fig. 1 Relationship between X-ray-induced mutations and spontaneous mutations of three lines selected for seven generations for speed of development and their control line. Means \pm s.e. are based on four replications. Correlation and regression coefficients are based on the angular values of the means of the fast, slow and control lines (connected by the straight line). Analysis of variance on such values indicated highly significant differences between lines and between the two types of mutations, but not between replications nor sex or for the interaction components. Numbers are the total number observed. $r = 0.997$; $P = 0.05$; regression coefficient = 3.275, s.e. = 0.242.

Fig. 2 Scatter diagram for the relationship between the two types of mutations of six wild populations of *T. castaneum*.

the control line (Fig. 1). This indicates that stabilising selection is efficient in producing genotypes that could stand sudden environmental changes (X ray), while these genotypes are less stable in normal environmental conditions. In other words, X rays have more effect on the wild strain (due to a certain degree of homozygosity) than the intermediate line (due to developmental homeostasis), while in stable environments spontaneous mutation is more pronounced in the intermediate line (due to induction of new recessive mutants) than the wild strain (due to greater genetic homeostasis). The different degrees of genetic and developmental homeostasis among different wild populations with different genetic backgrounds will undoubtedly affect the relationship between spontaneous and induced mutations observed among these populations (Fig. 2).

Artificial deciliation causes loss of calcium-dependent responses in *Paramecium*

WHEN a paramecium collides with an obstacle, it reverses the direction of the effective stroke of its cilia, swims backwards for a while, and, with one or more repetitions of this 'ciliary reversal' response, avoids the obstacle¹. When the medium is disturbed² or when the posterior part of its body is stimulated mechanically, it swims faster than usual and

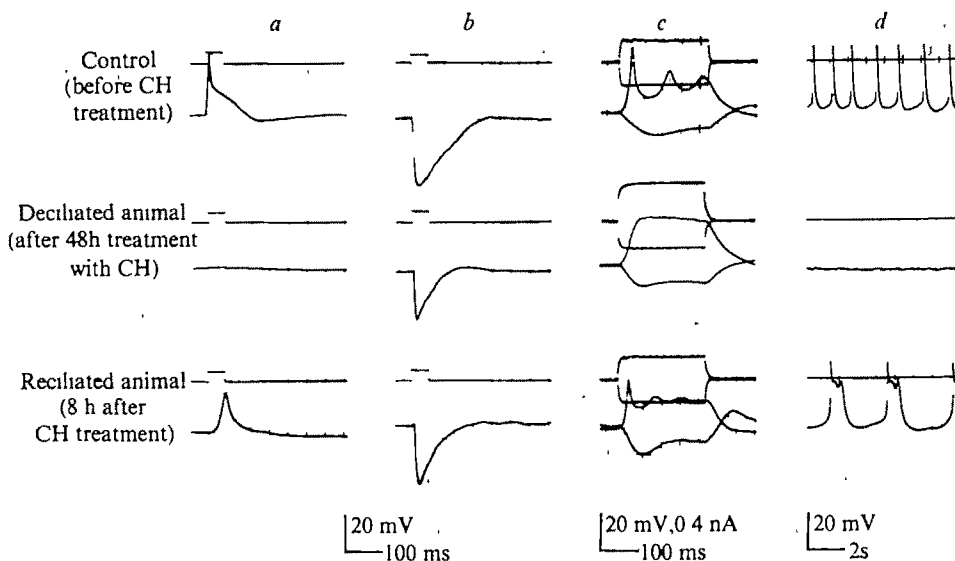

Fig. 1 *P. caudatum*, reared in hay infusion and washed in the adapting solution, which consisted of 2 mM CaCl_2 , 1 mM KCl and 1 mM Tris-HCl, pH 7.4, was deciliated with CH, which was added to the adapting solution at 5 mM. The animals were kept for about 48 h in this solution at 20°C . *a*, *b*, and *c*, Membrane potentials were recorded in the adapting solution at $20 \pm 2^\circ\text{C}$; *d*, recordings were made in a solution of 2 mM BaCl_2 , 1 mM CaCl_2 and 1 mM Tris-HCl, pH 7.4, $20 \pm 2^\circ\text{C}$. For recording, a glass capillary microelectrode, filled with 0.3 M KCl and with a resistance of 200–400 M Ω was used. Specimens that showed gradual depolarisation of the resting membrane potential were discarded. Successful recordings were made from about 120 specimens. *a*, Responses to mechanical stimuli given to the anterior end of the animal by means of a glass stylus with a rounded tip mounted on a piezoelectric phonograph cartridge. In each record the upper trace indicates the zero potential level as well as the electric pulse used to drive the stylus. *b*, Responses to mechanical stimuli given to the posterior end. The methods of stimulation and recording are the same as in *a*. *c*, Responses to direct current pulses applied through an intracellular electrode. The upper traces in each record indicate both the zero potential level and the applied current. In the case of the deciliated animal, the current was increased to exclude the possibility of change in the threshold of the regenerative response. *d*, Spontaneous membrane activity in Ba^{2+} - Ca^{2+} mixture. The upper trace in each record shows the zero potential level.

escapes from the stimulus mainly by increasing the frequency of ciliary beat. The current view of the underlying mechanisms can be summarised as follows^{3,4}. A mechanical stimulus to the anterior end of the animal deforms the cell membrane of this region, increasing the permeability to Ca^{2+} and causing a depolarisation which further activates the Ca^{2+} -channels in the membrane. Thus, the depolarisation develops regeneratively towards the equilibrium potential of Ca^{2+} . The Ca^{2+} which has entered the cell acts on some mechanism controlling the direction of ciliary beat to bring about ciliary reversal. On the other hand, a stimulus to the posterior end activates the K^{+} -channels in the membrane, causing hyperpolarisation and an increase in ciliary beat frequency. Although the animal behaves as a mechanoreceptor cell in the early stages of these events, it is not clear which part of the cell transduces the mechanical stimulus to the activation of Ca^{2+} - or K^{+} -channels. We report here the effect of removal of cilia on the electrophysiological responses of paramecium to mechanical as well as some other stimuli.

Paramecium caudatum was deciliated by treatment with chloral hydrate (CH) according to the method of Kuźnicki⁵. The methods of stimulation and recording were similar to those of Naitoh and Eckert⁶. Typical results are shown in Fig. 1.

Figure 1*a* and *b* shows membrane responses to mechanical stimuli, given by a fine glass stylus to the anterior and posterior ends of the animal, respectively. Untreated paramecia responded with depolarisation to anterior stimulation and with hyperpolarisation to posterior stimulation. When the animals were incubated in medium containing 5 mM CH, they lost the ability to swim within 24 h and sank to the bottom of the incubating glassware. Under a light microscope, the cilia appeared unimpaired in both number and individual length at this stage, but their movement was uncoordinated. Electrophysiological responses to mechanical stimulation were not significantly different from those of the untreated animal. As incubation continued, the cilia began to drop off, and in about 48 h all were lost except for

those in the oral groove. The deciliated paramecia retained the hyperpolarising response to posterior stimulation, but did not show a depolarising response to anterior stimulation. A stronger stimulus (obtained by pushing the stylus from a shorter distance) caused hyperpolarisation even if given to the anterior end. This eliminates the possibility of a general decrease in responsiveness. The resting membrane potential was not affected by CH. If a deciliated paramecium was transferred to medium containing no CH, cilia regenerated completely in 6–8 h. The reciliated paramecia responded with depolarisation to anterior stimulation, although both the amplitude and the rate of increase of the response were smaller than normal for some hours after the apparent completion of reciliation.

The finding that the depolarising responses disappear and reappear in parallel with the loss and the regeneration of cilia can be interpreted most readily if it is assumed that the Ca^{2+} -channels are localised in the ciliary membrane, whereas the K^{+} -channels are not. Although the possibility cannot be ruled out that CH inhibits Ca^{2+} -channels in the extraciliary membrane independently of the deciliating effect, it seems unlikely that the time course of such inhibitory effects coincides with that of the deciliating effect. The interpretation that the Ca^{2+} -channels are lost by deciliation is supported by two further experiments.

Figure 1*c* shows responses to current pulses applied through a second intracellular microelectrode. Fluctuations in potential (peaks) superimposed on the passive depolarisation are seen in the untreated animal. These have been ascribed to the regenerative activation of Ca^{2+} -channels⁷. This response also disappeared with deciliation and reappeared with reciliation. Similar results have recently been reported by Dunlap and Eskert^{8,9} who found that deciliation by vigorous agitation of *P. caudatum* incubated in CH eliminates the 'calcium response' to a depolarising current pulse, while regrowth of the cilia restores the response. They also interpret the results as indicating the localisation of Ca^{2+} -channels in the ciliary membrane.

Figure 1*d* shows spontaneous periodic depolarisations

observed in a solution containing Ba^{2+} and Ca^{2+} . This response is believed to depend on Ba^{2+} moving into the cell through the Ca^{2+} -channels¹⁸. The Ba^{2+} -response also disappeared and reappeared in parallel with deciliation and reciliation, although the frequency and the form of potential changes were altered somewhat in the reciliated animal.

Electron microscopic studies on paramecia have shown that binding sites for divalent cations are localised in the basal region of each cilium¹¹⁻¹³. Plattner suggested that the granular patches of these divalent cation-binding sites have a role in the regulation of ciliary movement by binding and releasing Ca^{2+} . It is interesting that with CH treatment the cilium is lost just proximal to these structures¹⁴. Although there is no evidence that these Ca^{2+} -binding sites are identical with the Ca^{2+} -channels, it is tempting to relate our results to these morphological findings.

During the preparation of our manuscript we learnt that Dr K. Dunlap, University of California, Los Angeles (personal communication), also observed, in *Paramecium caudatum*, loss of the regenerative component of membrane response by CH deciliation and its recovery with reciliation.

Two populations of heterozygote erythrocytes in moderate hypoxanthine guanine phosphoribosyltransferase deficiency

THE X-linked condition hypoxanthine guanine phosphoribosyltransferase (HGPRT) deficiency may be either gross or moderate in degree and is invariably associated with overproduction of urate in the hemizygote¹⁻³. In addition, however, the gross deficiency state (Lesch-Nyhan syndrome)³ also manifests with mental deficiency, choreoathetosis, spasticity and self-mutilation. Fibroblasts from heterozygotes for the gross deficiency state display mosaicism, some having normal HGPRT activity and others the reduced HGPRT activity characteristic of the hemizygote⁴. However, HGPRT activity in erythrocyte lysates from such heterozygotes is normal. Heterozygotes for the moderate HGPRT deficiency state, on the other hand, have HGPRT activity in erythrocyte lysates ranging between 20% of normal and completely normal values⁵. To elucidate this, we have developed an autoradiographic procedure to show HGPRT activity in individual erythrocytes. In families with moderate HGPRT deficiency, in whom erythrocytes of the hemizygote were not significantly labelled by this procedure, heterozygotes showed two erythrocyte populations, one deficient in HGPRT and one containing HGPRT activity. On the other hand, in families whose HGPRT deficiency was gross and manifested as the Lesch-Nyhan syndrome, heterozygotes showed only the normal pattern of labelling. Thus, mosaicism was present in erythrocytes from heterozygotes for moderate, but not for gross, HGPRT deficiency. The former

finding supports the Lyon hypothesis⁶ whereas, the latter finding suggests that either the X chromosome carrying the mutant HGPRT gene is preferentially inactivated, or the X chromosome is randomly inactivated with later selection against the erythrocyte precursors containing the mutant HGPRT enzyme.

Normal nucleated cells incorporate tritiated purine bases into nucleic acids, permitting autoradiographic demonstration of the presence of HGPRT activity⁷. Erythrocytes also contain considerable amounts of HGPRT and, although they are capable of accumulating significant quantities of labelled mononucleotides, they do not synthesise nucleic acids. Earlier attempts to demonstrate HGPRT activity in erythrocytes by autoradiography failed because the soluble mononucleotides, unlike nucleic acids, are lost immediately the selective permeability of the cell membrane is destroyed by fixing or drying the cells. Thus, the demonstration of HGPRT activity in erythrocytes by autoradiography using the conversion of tritiated hypoxanthine to nucleotide required fixation of the labelled inosinic acid *in situ*. We have done this by precipitation of the mononucleotides by lanthanum, as developed by Bakay⁸, simultaneously with fixation of the red cells by osmium tetroxide. After autoradiography, silver grains were counted over 200 cells and the distribution of the grain counts per cell was plotted. The distribution of counts in normal subjects showed that at least 90% of erythrocytes had more than five grains per cell; in Lesch-Nyhan subjects, no erythrocytes had more than this value. The grain counts per cell were therefore combined into three groups (Fig. 1). To validate the method, the distribution of grain counts was studied in artificial mixtures of erythrocytes from a normal subject and one with the Lesch-Nyhan syndrome. The results enabled the proportions of the two types of cell to be confirmed (Fig. 1) and thereby justified the search for two populations of erythrocytes in heterozygotes.

Members of one family with the Lesch-Nyhan syndrome and three families with less severe HGPRT deficiency were studied by this technique (Fig. 1). The HGPRT activity in cell-free lysates of erythrocytes and fibroblasts from hemizygotes and heterozygotes for each of these families is shown in Table 1. In family W (Lesch-Nyhan syndrome)⁹, erythrocytes from two obligate heterozygotes, both of whom showed normal activity in an erythrocyte lysate, showed a uniform pattern of labelling indistinguishable from normal. In hemizygotes from families L and C¹⁰, erythrocytes were indistinguishable from those of the Lesch-Nyhan syndrome. The heterozygote in family L, whose HGPRT activity in an erythrocyte lysate (Table 1) indicated that, if there were two populations, 90% of her erythrocytes would contain mutant HGPRT enzyme^{*}, showed 86% of

Table 1 Hypoxanthine phosphoribosyltransferase activity in cell lysates (nmol per mg protein per h)

W (Lesch-Nyhan)	Hemizygote	< 0.01	< 1
	Heterozygote 1	89	70
	Heterozygote 2	85	88
L	Hemizygote	< 0.05	7
	Heterozygote	10	103
C	Hemizygote	< 0.05	27
	Heterozygote	44	46
B	Hemizygote	13	30
	Heterozygote	18	60
Normal \pm s.d.		101 \pm 12	157 \pm 32

*Percentage of erythrocytes containing mutant HGPRT enzyme =

$$\frac{A_N - A_H}{A_N - A_M} \times 100$$

where A_N is HGPRT activity in normal erythrocyte lysate, A_M is activity of mutant HGPRT enzyme in erythrocyte lysate from hemizygote, and A_H is HGPRT activity in erythrocyte lysate from heterozygote

erythrocytes with less than five grains per cell. In the heterozygote from family C, the expected percentage of HGPRT-deficient erythrocytes was 56% and a value of 70% was observed. These results were taken to confirm the presence of two populations of erythrocytes in heterozygotes for the moderate HGPRT deficiency syndrome.

The fourth family, B, had the least severe HGPRT deficiency (Table 1) and the least severe clinical manifestations¹⁰. However, the pattern of grain counts over the erythrocytes of the hemizygote was close to normal, although there were more cells with less than five grains per cell than were seen normally. The autoradiographic procedure was therefore modified by reducing the duration of incubation and extending the exposure time. This modification did not significantly alter the pattern of labelling in normal erythrocytes, but it resulted in 86% of the erythrocytes from the hemizygote showing less than five grains per cell. Erythrocytes from the heterozygote of this family also showed a similar proportion of HGPRT-deficient cells, a finding expected from the HGPRT activity of her erythrocyte lysate. This technique has therefore demonstrated the expected

proportion of normal and HGPRT-deficient erythrocytes in heterozygotes from families with moderate HGPRT deficiency. It would seem that in the functionally less severe HGPRT mutations, random inactivation of the X-chromosome occurs and two types of erythropoietic clones result, one of which produces normal erythrocytes and another which produces erythrocytes containing mutant HGPRT enzyme.

In the severe HGPRT deficiency of the Lesch-Nyhan syndrome, on the other hand, although the technique could identify the reduced HGPRT activity of the mutant enzyme, no HGPRT-deficient erythrocytes were detected in two heterozygotes whose heterozygosity had been established by both the production of affected sons and autoradiography of fibroblasts. Although two populations of fibroblasts are found in heterozygotes for the Lesch-Nyhan syndrome, all previous studies have demonstrated normal HGPRT activity in erythrocyte lysates, and several other studies have suggested that the X chromosome of all of their erythrocyte precursors was normal¹¹⁻¹³. The present technique provides direct confirmation of this. Either inactivation of the X chromosome is not random in these cells

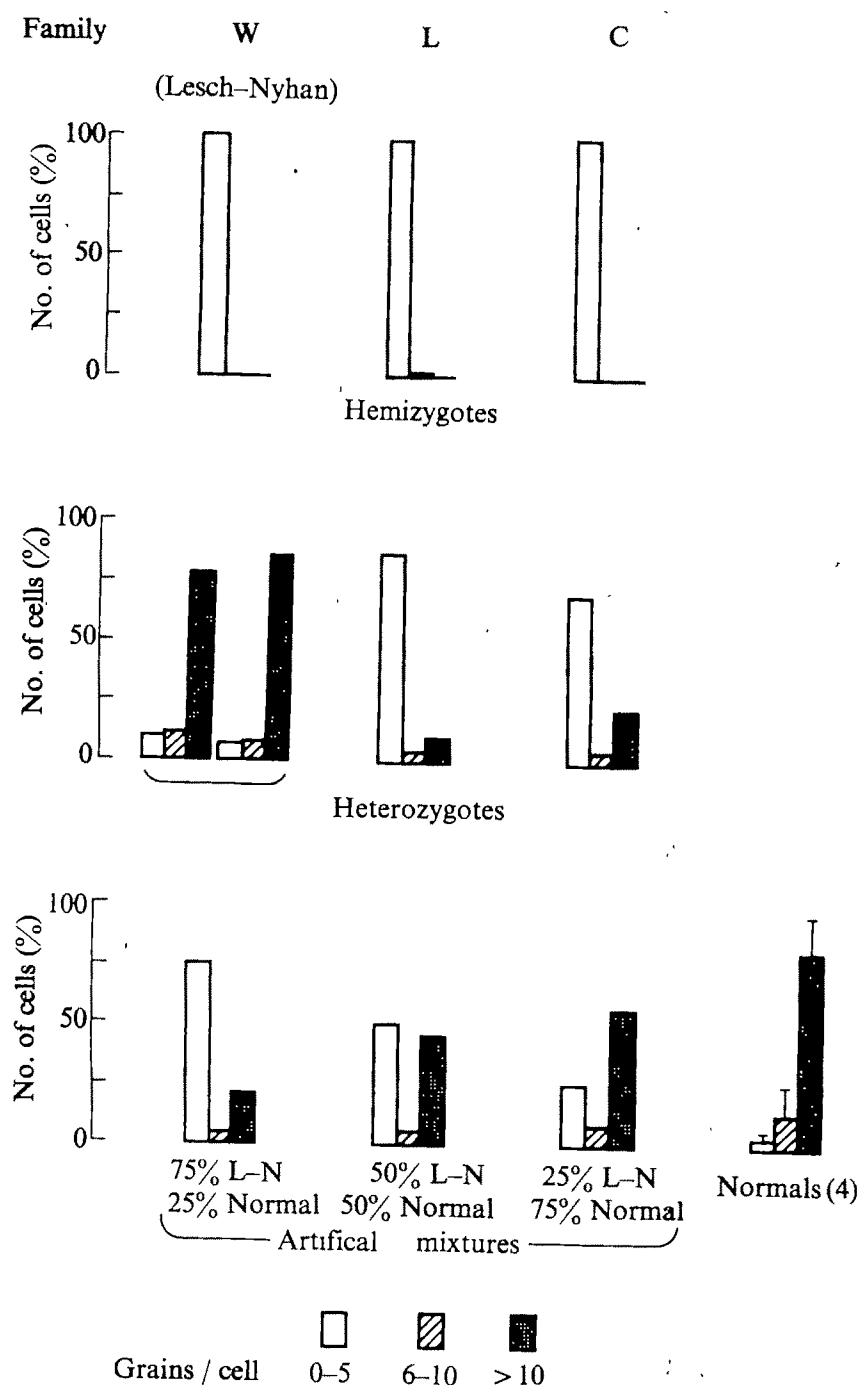

Fig. 1 Comparison of grain counts per cell in autoradiographs of erythrocytes from normal subjects, from hemizygotes and heterozygotes from three families with HGPRT deficiency and in artificial mixtures of normal and HGPRT-deficient erythrocytes. Erythrocytes were incubated with labelled precursor in a special incubation chamber constructed by cementing a glass ring to a cover slip with Araldite. The incubation mixture contained 0.05 M sodium phosphate (pH 7.4), 0.075 M sodium chloride, 5 mM glucose and 0.05 mM ³H-hypoxanthine [1 Ci mmol⁻¹ (Amersham) 99% pure on electrophoresis]. Aliquots (200 μ l) of the incubation mixture were pipetted into the incubation chamber, and 5 μ l of a 1:100 saline dilution of heparinised and washed packed erythrocytes was added and mixed by swirling. An acid-washed glass microscope slide was then placed over the incubation chamber, and the whole slide and chamber were then inverted and incubated in an humidified atmosphere at 37°C for 30 min. During the incubation, the cells settled and became firmly attached to the slide; the glass ring and coverslip prevented spreading of the cell suspension. The wide separation of cells on the slide also prevented any possible cell-to-cell transfer of labelled material. After incubation, the chamber was removed and the slide immediately washed thoroughly to remove all traces of labelled hypoxanthine, care being taken to cover the cells at all times with a layer of saline. After washing, the slides were flooded with a fixative consisting of 1 volume of 0.1% osmium tetroxide and 9 volumes of 0.12 M neutral lanthanum chloride (0.12 M lanthanum chloride neutralised with lanthanum oxide and filtered). After fixation for 15 min, the slides were washed repeatedly with distilled water and allowed to dry. The dry slides were immersed in absolute methanol for 1 h, washed with methanol and dried. The slides were then coated with photographic emulsion (Kodak NTB 2) and exposed for 3 d. After development, the slides were stained with 0.5% aqueous eosin for 10 min, washed with water, destained in a solution containing 50% methanol and 50% citrate phosphate buffer (4 volumes 0.1 M citric acid + 6 volumes 0.2 M disodium hydrogen phosphate) for about 15 s and immediately washed with absolute methanol and dried. The autoradiographs were permanently mounted before grain counting. Control slides using normal erythrocytes were examined with each batch of cells studied.

or there is subsequent selection against haemopoietic precursor cells containing mutant HGPRT enzyme. Support for such selection against HGPRT-deficient stem cells *in vivo* in heterozygotes for the Lesch-Nyhan syndrome, has been provided by studies of the culture characteristics of their bone marrow cells¹⁴. Our findings further suggest that, whereas there exists a wide spectrum of severity of HGPRT deficiency, there is a critical intracellular level of HGPRT activity which, in the hemizygote, leads to the Lesch-Nyhan syndrome and which, in the heterozygote, renders affected erythrocyte precursors at a marked functional disadvantage in comparison with the normal.

Glucocorticoid receptors in murine embryonic facial mesenchyme cells

In various experimental animals, clefting of the developing secondary palate can be induced by the administration of glucocorticoids to pregnant animals¹⁻⁴. Various inbred strains of mice exhibit different degrees of susceptibility to glucocorticoid-induced cleft palate⁵⁻⁷. Specifically, A/J mice

treated with glucocorticoids between days 11 and 14 of gestation (day of detection of vaginal plug designated day 0 of pregnancy) produce 100% of their offspring with cleft palate, whereas C57BL/6J (C57) mice similarly treated produce offspring with only 20-25% cleft palate. Although it has been demonstrated that glucocorticoids can elicit divergent physiological responses in various differentiated cell types through a class of specific cytoplasmic and nuclear receptor proteins⁸⁻¹¹, the exact molecular mechanism(s) by which glucocorticoids function as teratogens as well as the aetiology of the strain-specific difference in the response to glucocorticoids are unknown. We present here evidence that mouse facial mesenchyme cells obtained either directly or in primary culture possess specific glucocorticoid-receptor proteins of high affinity and limited capacity for dexamethasone. Furthermore, we report that A/J facial mesenchyme cells possess approximately double the amount of receptor proteins than C57 mesenchyme cells.

Embryos were obtained from day 14 pregnant A/J or C57 mice (purchased timed pregnant from Jackson Laboratories and obtained on day 11 of pregnancy). Embryos were dissected from the uteri in phosphate-buffered saline (PBS). Placentae and other extraembryonic membranes were removed, and the embryos were washed in PBS. Secondary palates or maxillary processes were dissected from the embryos and pooled. Minced tissues were dissociated with 0.25% trypsin (Difco) containing 0.1% EDTA (Fisher Scientific) for 10 min at 37 °C on a shaking water bath. After dissociation, NCTC-109 medium (Microbiological Associates) containing 10% foetal calf serum (Gibco), streptomycin (100 µg ml⁻¹, Gibco) and penicillin (100 units ml⁻¹, Gibco) was added at 4 °C to inhibit the trypsin. Cells were dispersed, washed and seeded into 75-cm² tissue culture flasks (Falcon) at a density of 5.4 × 10⁴ cells per cm². Cells were grown in NCTC-109 medium containing 10% foetal calf serum and antibiotics. Cultures of mesenchyme cells obtained from either the secondary palate or maxillary processes appeared to have a fibroblastic morphology.

Cell suspensions were incubated for 40 min at 37 °C with ³H-dexamethasone to measure glucocorticoid receptor activity since fluorinated glucocorticoids in contrast to the naturally occurring corticosteroids do not bind to serum transcortin (CBG)¹², a component of foetal calf serum. Under these conditions, steroid uptake was maximum for both A/J and C57 mesenchyme cells. Figure 1 illustrates one of several experiments in which the specific binding of ³H-dexamethasone to whole cell suspensions of A/J or C57

Fig. 1 At confluency (approximately 4–5 d after seeding), cells (1.5×10^6 per cm^2 at confluency) were trypsinised (0.1% trypsin), centrifuged and washed in Dulbecco's modified PBS at 4°C (Ca^{2+} and Mg^{2+} free, 0.01% EDTA, 0.02% dextran). Glucocorticoid-receptor activity of both cytoplasmic and nuclear origin was measured in whole cell suspensions using 1, (2)- ^3H -(N)-dexamethasone (specific activity 28 Ci mmol^{-1} ; Amersham/Searle) as a probe according to the method of Baxter *et al.*¹² as modified by Sibley and Tomkins¹³. Approximately 3×10^6 cells obtained from A/J (○) or C57BL/6J (●) maxillae were incubated in 0.5 ml warm (37°C) serum-free NCTC-109 medium containing $1\text{--}60 \text{ nM}$ ^3H -dexamethasone in the absence or presence of an excess of unlabelled dexamethasone (10^{-6} M) in parallel assays to correct for nonspecific binding¹⁴. Cell suspensions were incubated at 37°C for 40 min on a shaking water bath and vortexed periodically. At the end of the incubation, aliquots were removed from each assay to calculate the total concentration of ^3H -dexamethasone, and the suspensions were chilled to 4°C . All subsequent procedures were carried out at 4°C . The cells were centrifuged at $800g$ for 5 min. The pellets were washed with 5.0 ml of PBS, recentrifuged, and resuspended in 0.5 ml of distilled water. The pellets were then freeze-thawed three times in an ethanol-dry ice bath. Aliquots of the lysates were either taken in duplicate and dissolved in 10 ml of scintillation fluid (Hydromix, Yorktown Research) and counted in a Packard Tri-Carb 3375 liquid scintillation spectrometer with an efficiency of 33% for ^3H to calculate the total amount of specifically bound ^3H -dexamethasone, or analysed for total cellular protein by the method of Lowry¹⁵ using bovine serum albumin as a standard. Inset, Scatchard plots¹⁶ of the binding data for ^3H -dexamethasone by suspensions of A/J (○) or C57BL/6J (●) maxillary mesenchyme cells.

primary mesenchyme cells (maxillary) was measured as a function of the free steroid concentration. The curves indicate the presence of specific corticosteroid receptors, for dexamethasone in both cell types, which approach saturation between $5 \times 10^{-8} \text{ M}$ and $2.5 \times 10^{-7} \text{ M}$ dexamethasone. Scatchard plots of the data (inset, Fig. 1) are linear, indicating the presence of a single class of binding sites for dexamethasone in both A/J and C57 mesenchyme cells with an apparent K_D for dexamethasone of $\sim 8.5 \times 10^{-8} \text{ M}$ and $1.3 \times 10^{-7} \text{ M}$ for A/J and C57 cells, respectively; and with 121 fmol of ^3H -dexamethasone bound per mg total cell protein and 54 fmol per mg cell protein for the two cell types. Table 1 represents cumulative data obtained from Scatchard plots¹⁶ from several experiments in

which the specific binding of ^3H -dexamethasone was measured in cell suspensions derived from primary cultures of either palatal or maxillary mesenchyme cells obtained from A/J or C57 embryos. Irrespective of the origin of the mesenchyme cells (that is palatal or maxillary), the amount of dexamethasone-receptor activity (cytoplasmic and nuclear) was consistently higher in the mesenchyme cells of A/J than in the corresponding C57 cells (\sim twofold). A/J or C57 mesenchyme cells derived from either the secondary palate or maxillary processes do not differ significantly in total protein per cell, in the distribution of protein in cytosol or nuclear fractions (Table 2), or in the amount of ^3H -dexamethasone which is distributed *in vitro* at 37°C between the cytoplasmic and nuclear fractions (33.1 compared with 39% in the nuclear fraction for A/J and C57 cells, respectively) in cultured or freshly trypsinised cells. Therefore, the difference in total amount of glucocorticoid-receptor proteins in A/J and C57 mesenchyme cells as measured by whole cell binding seems to be partially accounted for by an apparent difference in the amount of dexamethasone-receptor protein(s) in the cytosols of A/J and C57 cells (see also Table 3).

Although C57 mesenchyme cells possess on average a lower concentration of dexamethasone-receptor proteins on a per cell basis (7,200 sites per cell compared with 16,300 sites per cell for A/J, calculated from the cell numbers), the apparent K_D for dexamethasone of the C57 receptors is higher, $\sim 7.9 \times 10^{-8} \text{ M}$, than the corresponding affinity of the receptors in the A/J cells for dexamethasone, $\sim 1.7 \times 10^{-8} \text{ M}$. The reason for these differences is not entirely apparent although a similar difference in the affinity constant for dexamethasone and quantitative differences in either the number or distribution of cytoplasmic and/or nuclear glucocorticoid receptors have been reported in cultured murine lymphosarcoma and L929 fibroblast cells between steroid-sensitive and resistant clones^{13,17–19}.

To determine whether these quantitative differences in dexamethasone-receptor activity between cultured A/J and C57 mesenchyme cells are due to alterations in the cells' ability to respond differentially in culture to certain growth factors which could alter the cell content of receptor proteins²⁰, dexamethasone-binding activity was measured in cytosol fractions prepared from the maxillary processes of 14-d-old embryos (Table 3). Although the absolute amount of ^3H -dexamethasone bound per mg cytosol protein in both A/J and C57 maxillary cytosols was six times less than the amount of ^3H -dexamethasone which was bound per mg total cell protein using whole cell suspensions (average 315 fmol of bound ^3H -dexamethasone per mg cell protein and 150 fmol per mg cell protein for cultured A/J and C57 cells, respectively), the dexamethasone-receptor activity was twice as high in the A/J maxillary cytosols (54.5 fmol bound ^3H -dexamethasone per mg cytosol protein) than in the C57 maxillary cytosols (23 fmol bound per mg cytosol protein). But the K_D for dexamethasone of the A/J cytosol receptor(s) ($\sim 2.9 \times 10^{-8} \text{ M}$) and for the C57 cytosol receptor(s) ($\sim 8.9 \times 10^{-8} \text{ M}$) were similar to those values estimated by using suspensions of cultured mesenchyme cells. Likewise, when freshly dissociated (trypsinised) A/J maxillary mesenchyme cells are labelled *in vitro*, they bind approximately three times as much dexamethasone (54 fmol bound ^3H -dexamethasone per mg cell protein) than the corresponding C57 mesenchyme cells (18 fmol bound ^3H -dexamethasone per mg cell protein). Therefore, the apparent difference in the amount of dexamethasone-receptor protein(s) between A/J and C57 mesenchyme cells is evident in cells which have either been freshly dissociated or grown in culture for several days. These results suggest that there is little or no loss of this phenotypic trait (receptor concentration) in primary cultures of mesenchyme cells.

These results demonstrate that mouse mesenchyme cells derived from either the secondary palate or maxillary pro-

Cumulative data from several different experiments (N , number of experiments) \pm s.e.m. showing the specific binding of ^3H -dexamethasone to receptors in whole cell suspensions. Data were analysed by the method of Scatchard¹⁶ to calculate the concentration of receptor-steroid complex (r) in equilibrium conditions and the affinity of the receptors for dexamethasone, dissociation constant (K_D). The protein content (P) was determined by the method of Lowry¹⁵. The number of sites per cell was calculated from the cell number, which was determined using a Coulter counter.

cesses possess cytoplasmic dexamethasone-binding proteins of high affinity and limited capacity. Furthermore, facial mesenchyme cells obtained from day 14 A/J embryos have on average approximately double the amount of receptor proteins than do mesenchyme cells obtained from C57 embryos at equivalent stages. This biochemical difference might partially account for the variations observed *in vivo* in the ability of these two strains of mice to respond differentially to the teratogenic effect of glucocorticoids.

The cytoplasmic dexamethasone receptors from A/J and C57 mesenchyme cells have biological activity in that cell suspensions labelled *in vitro* with ^3H -dexamethasone accumulate specifically bound radioactive steroid in their nuclei, presumably as a result of nuclear translocation¹⁴. The number of dexamethasone-receptor sites per cell as well as the percentage of ^3H -dexamethasone which is trans-

Table 2 Distribution of ^3H -dexamethasone binding in cytosol and nuclear fractions of mouse maxillary mesenchyme cells

Strain	Receptor activity Cytosol fraction	Nuclear fraction	% Nuclear transfer
A/J	97.7*	20.6	17.4(39.1)
	16†	15.2	48.7(34.3)
			Average: 33.1(36.7)
C57BL/6J	160*	103	39.2(33.1)
	33†	20.9	38.8(31.0)
			Average: 39 (32.1)

Whole cell suspensions from either freshly dissociated maxillary cells ($\sim 20 \times 10^6$ cells)* or primary mesenchyme cultures ($\sim 4 \times 10^6$ cells)† were incubated with $10 \text{ nM } ^3\text{H}$ -dexamethasone in the absence or presence of unlabelled dexamethasone (10^{-5} M) at 37°C for 40 min. The cells were then centrifuged, washed in ice-cold PBS, recentrifuged and resuspended in 1.0 ml of hypotonic buffer, composed of 10 mM Tris-HCl , $\text{pH } 8.0$, 1 mM MgCl_2 and 2 mM CaCl_2 , and lysed by freeze-thawing. The lysates were separated into crude nuclear pellets and crude cytosol supernatants after centrifugation ($200g$, for 5 min at 4°C). Aliquots of the latter were taken to assess the specific binding of ^3H -dexamethasone to cytosol fractions and to determine the protein content. The nuclear pellets were resuspended in 40 ml of ice-cold hypotonic buffer and centrifuged. The pellets were dissolved in 0.5 ml of distilled water and aliquots were taken to assess the specific binding of ^3H -dexamethasone in the nuclear fractions and to determine the protein contents. Receptor activity is expressed as fmol of specifically bound ^3H -dexamethasone per mg of cytosol or nuclear proteins. The percentage of nuclear transfer of the dexamethasone-receptor complex was determined according to Croce *et al.*²³ using the following formula:

$$\% \text{ nuclear transfer} = \frac{\text{fmol per mg nuclear proteins}}{\text{fmol per mg nuclear proteins} + \text{fmol per mg cytosol proteins}} \times 100$$

Values in parentheses represent the percentage of total cellular protein in the nuclear fractions.

Table 3 Characteristics of dexamethasone receptors in cytosols of maxillary processes

Strain	A/J	C57BL/6J
$N = 2$	$K_D = 2.9 \times 10^{-8} \text{ M}$ (± 2.2) $r = 54.5 \text{ fmol per mg}$ cytosol protein (± 1.5)	$N = 3$ $K_D = 8.9 \times 10^{-8} \text{ M}$ (± 2.6) $r = 23 \text{ fmol per mg}$ cytosol protein (± 6.7)

Pooled maxillary processes obtained from day 14 embryos were homogenised in 2.0 ml of buffer composed of 10 mM Tris-HCl , $\text{pH } 7.4$, 1.5 mM EDTA and $0.5 \text{ mM dithiothreitol}$ in a Kontes homogeniser (20–25 strokes) at 4°C . After homogenisation, sucrose was added to a final concentration of 0.5 M . Homogenates were centrifuged at $100,000g$ for 60 min at 4°C . Aliquots of the supernatants (cytosol fraction) were incubated at 4°C for 2 h with $1\text{--}100 \text{ nM } ^3\text{H}$ -dexamethasone in the absence or presence of an excess of unlabelled dexamethasone (10^{-5} M) to correct for nonspecific binding²¹. A suspension of dextran (0.5%, dextran T-70, Sigma) coated charcoal (5.0%, activated charcoal, Sigma) was then added to each assay to separate free from protein-bound steroid. The tubes were centrifuged at $1,500g$ for 15 min at 4°C , and aliquots of the supernatants were taken to assess the specific binding of ^3H -dexamethasone to cytosol proteins. The values in the table represent the average data obtained from Scatchard plots for each experiment (N , number of experiments) \pm s.e.m.

ferred into the nucleus in A/J and C57 is in agreement with the values reported for other steroid-responsive cells in culture^{18,21,22}. The presence of functional glucocorticoid receptors in both the palatal and surrounding facial mesenchyme cells favours the likelihood that these cells have the capacity to respond biologically to physiological levels of glucocorticoids. In fact, unmetabolised cortisol has been localised in the cells of the foetal maxilla of day 12 A/J embryos after *in vivo* administration of ^3H -cortisol²³.

Glucocorticoids are known to inhibit the growth of primary cultures of rat, mouse and chick embryonic fibroblasts^{24–26} as well as the multiplication of established mouse fibroblast lines such as L929 (ref. 27). Cortisone can also inhibit *in vivo* the proliferation of mesenchyme cells in the developing mouse secondary palate in A/J and H-Velaz mice^{28,29}. Experiments are in progress to determine whether the growth of primary cultures of mouse facial mesenchyme cells is altered *in vitro* by glucocorticoids.

We thank Chad Leyshon for technical assistance.

Reactivity of normal and brachypod mouse limb mesenchymal cells with con A

SINCE plant lectins, such as concanavalin A (con A) and wheat germ agglutinin (WGA), bind to specific carbohydrate residues¹, they have been used to investigate changes in plasma membranes during the course of normal development by monitoring lectin-induced agglutinability²⁻⁴, the binding affinities of carbohydrate moieties of cell-surface components for radioactively-labelled lectins^{3,5,6}, and the distribution of binding sites using fluorescently conjugated lectins⁷. It has been proposed that agglutinability with con A and WGA varies with the stage of differentiation of a

particular cell type^{1,2,5,6,8}. It seems reasonable to assume, therefore, that modifications of cell-surface structure, such as changes in carbohydrate components or in their distribution on or in the plasma membranes, could result in the manifestation of an aberrant phenotype. Support for this notion comes from studies in which a reduced affinity for insulin and various plant lectins by liver cell plasma membranes was observed in young, hyperglycaemic mice⁹. Several studies on hereditary skeletal disorders¹⁰⁻¹² including brachypodism (*bp*^H) in mice^{13,14} have suggested that these anomalies originate at a time when the surface-mediated events of cell recognition and sorting-out are resulting in the formation of prechondrogenic blastemata¹⁵. Since rudiments derived from the postaxial region of the hindlimbs are the most severely affected in brachypodism^{12,14} con A agglutination and binding experiments were carried out on mesenchyme cells from this region in both normal (+/+) and mutant (*bp*^H/*bp*^H) embryos during early limb development. The results presented here show that differences occur over the 3-d test period supporting the contention that plasma membrane surfaces change during developments^{1-6,8}. These developmental modifications are, however, temporally different between the two genotypically different cells which may be related to the ultimate manifestation of the abnormal phenotype.

Postaxial mesenchyme cells of 11-d stage embryos of both genotypes exhibited a similar degree of agglutination (Table 1). Cells from 12-d stage normal embryos, however, showed a significant reduction in agglutination, whereas agglutination of the brachypod cells remained essentially unchanged. It is during this period that myogenic and chondrogenic processes commence in normal mouse limb development²². The decreased agglutination exhibited by 12-d stage normal cells is in agreement with the contention that, as differentiation proceeds, con A and WGA agglutinability decreases^{1,8}.

A reduction similar to that observed in normal cells between the 11- and 12-d stages was not found until 24 h later

Table 1 Comparison of con A binding and agglutination of normal and brachypod limb mesoblast cells from 11-, 12-, and 13-d stage mouse embryos*

* Mutant and normal mesoblast cells from the postaxial region of the hindlimbs of 11-, 12-, and 13-d stage embryos were isolated as described previously¹⁸. After a 30-min treatment with Ca²⁺ and Mg²⁺-free (CMF) Tyrode's solution, dissociation was carried out in phosphate-buffered saline (PBS)¹⁷ containing 10 µg ml⁻¹ DNase³. In certain experiments, CMF treatment was replaced by a 20-min treatment with 1.5% trypsin at room temperature. Both types of dissociation treatments yielded cell suspensions of greater than 92% viability as determined by Trypan blue exclusion. Viability remained the same at the end of the experiments. Binding and agglutination experiments were carried out in the following conditions: a 0.4-ml reaction mixture containing 150 µg ml⁻¹ con A (Sigma) and 5.5 × 10⁶ cells in PBS-DNase solution was incubated in Falcon multiwell culture dishes for 20 min at 4 °C with occasional, gentle swirling. Controls for each genotype included 0.1 M α-D-methylmannose (Sigma) to inhibit lectin-induced agglutination. Aliquots of each reaction mixture were placed in depression slides and the percentage of total cells agglutinated (two or more cells in clumps) was determined by counting single cells against agglutinated cells in a minimum of six fields of view¹⁷. Statistical significance of the differences was determined using a two-group comparison *t* test¹⁸. Tritiated con A (New England Nuclear, 65.2 Ci mmol⁻¹) diluted with cold con A to a concentration of 150 µg ml⁻¹ was used for the binding experiments. Labelled cells were collected as described by Noonan and Burger¹⁸ and solubilised in Protosol (New England Nuclear) before counting in Omnifluor-toluene scintillation cocktail with a Beckman LS-100 scintillation counter. Protein determinations were carried out using Duly and Grieve's modification of the Lowry procedure^{20,21}.

† Expressed as percentage agglutination over that found in controls.

‡ Expressed as c.p.m. × 10⁻³ above what was determined for the controls.

§ Average value for at least three determinations.

¶ CMF-treated, 12-d *bp*^H/*bp*^H significantly different from CMF-treated, 12-d +/+ but did not differ significantly from 12-d trypsinised +/+ or *bp*^H/*bp*^H (two-group comparison *t* test, *P* = 0.01).

in the mutant cells (Table 1). This delayed decrease in agglutination corresponds with the delay in the ability of mutant cells to produce matrix components and stain meta-chromatically in the intact limb^{13,14}, in monolayer cultures¹⁶, and in rotation-reaggregation cultures²². It has been shown in other developing systems that the decrease in con A-induced agglutination is not accompanied by a concomitant drop in the binding of the lectin^{1,5}, suggesting that the decrease in agglutinability is due to the inability of the binding sites to rearrange into a display conducive to agglutination¹. This does not, however, seem to apply to this system (Table 1). There is a decrease in the amount of con A bound by the +/+ cells between days 11 and 12, whereas the mutants remain essentially the same. Comparing the specific activities of con A bound to bp^H/bp^H and that of +/+ at day 11, both genotypes bind approximately the same amount of lectin. The decline in the binding of con A by the +/+ cells at day 12 results in an increase in the ratio of specific activities, suggesting that twice as many binding sites are in bp^H/bp^H cells than in +/+ cells of the same gestational age. At day 13 the amount of lectin bound to bp^H/bp^H cells again approaches the normal condition. It is unlikely that the variations in binding can be explained solely by changes in surface area since this remained essentially unchanged in the two genotypes over the 3 d tested (Table 1).

The question remains as to whether the decrease in binding exhibited by the +/+ cells at day 12 is the result of loss of sites or masking of sites. Studies with trypsinised cells of both genotypes at day 12 (Table 1) supports the latter contention since the amount of tritiated lectin bound is the same with both trypsinised cell types. Enzyme-treated +/+ cells also exhibit the same degree of agglutination as trypsinised and non-trypsinised bp^H/bp^H cells. This supports the once held notion that trypsinisation unmasks "cryptic" sites²⁴ and suggests that 12-d stage +/+ and bp^H/bp^H cells possess the same number of con A-binding sites.

It is not understood at this time what the relationship is between the degree of agglutination, con A-binding sites, and the effect of the bp^H mutation. Work is presently in progress to determine agglutination with other plant lectins (WGA, fucose-binding protein) as well as the distribution of their respective binding sites using fluorescent conjugated lectins. Also, investigations using phenotypically normal bp^H /+ offspring are being carried out to determine the degree of functionality of the bp^H allele in the heterozygous condition.

Genetic differences in susceptibility of pancreatic β cells to virus-induced diabetes mellitus

INFECTION of certain inbred strains of mice with the M variant of encephalomyocarditis (EMC) virus produces β -cell damage and a diabetes-like syndrome^{1–4}. The development of this syndrome is genetically determined and susceptibility is inherited as an autosomal recessive trait^{5,6}. The genetic factors involved seem to act at the level of the β cells, and *in vitro* studies have shown that β cells from susceptible strains of mice are more permissive to EMC infection than β cells from resistant strains of mice⁷. We have investigated first, the capacity of EMC virus to replicate in β cells from F₁ and F₂ offspring of susceptible and resistant strains of mice, and second, the effect of the viral infection on the level of insulin and glucose in the blood.

Four-to-five-week-old mice susceptible (SWR/J) and resistant (C57BL/6J) to the development of EMC-induced diabetes^{5,6}, as well as the F₁ and F₂ offspring, were infected intraperitoneally with 5.0×10^3 plaque-forming units (PFUs) of the M variant of EMC virus. At different times after infection, the pancreas was removed and β cells were isolated from individual mice as before⁷. In brief, the pancreas was minced, treated with collagenase (3 mg ml⁻¹ for 15 min at 37°C) and approximately 100 islets were collected from each pancreas with a stereo microscope. The islet-containing material was again treated with collagenase (7 mg ml⁻¹ for 6 min at 37°C), filtered through sterile gauze to remove large aggregates, and then layered on a 13–36% preformed Ficoll density gradient. The heavy visible band containing approximately 6.0×10^4 cells was collected⁷. Staining with aldehyde-thionin or fluorescein isothiocyanate-labelled anti-insulin antibody showed that almost 85% of the cells were β cells. These cells were then washed, frozen and thawed three times, homogenised and assayed for infectious virus on confluent monolayers of secondary mouse embryo cells. The concentration of insulin in the plasma was measured by the double antibody radioimmunoassay technique⁸ using mouse insulin (Novo A/S, Copenhagen) as the standard. Blood glucose levels were determined enzymatically by the glucose oxidase method with *o*-dianisidine dihydrochloride as the reactive dye⁹.

Figure 1 shows the relationship between insulin and glucose levels in the plasma at different times after infection. Before infection, the mean blood glucose level was 147 ± 19 mg per 100 ml with none of the glucose values above 182 mg per 100 ml or below 103 mg per 100 ml. The mean insulin level was 3.0 ± 0.95 ng ml⁻¹ with none of the insulin values below 1.9 ng ml⁻¹ or above 5.7 ng ml⁻¹. Within 48 h after infection, almost two-thirds of the SWR/J mice had insulin and glucose values outside these ranges. At 7 d, and even more clearly at 14 d, many of these mice became hypoinsulinaemic and hyperglycaemic. In contrast to the SWR/J mice, the glucose and insulin values of the C57BL/6J and F₁ hybrids generally fell within the normal range. Occasionally, 2 d after infection, a small percentage of the F₁ hybrids showed signs of hyperinsulinaemia, but this generally was not followed by hypoinsulinaemia. Several F₂ mice also showed signs of hyperinsulinaemia and hypoglycaemia 2 d after infection, but in contrast to the F₁ hybrids, at 7 and 14 d they became segregated into two groups—one with glucose and insulin levels within the normal range and the other showing severe hypoinsulinaemia and hyperglycaemia.

The viral titre in β cells isolated from mice at different times after infection is illustrated in Fig. 2. Data from 290 individual mice show that the greatest difference between SWR/J and C57BL/6J

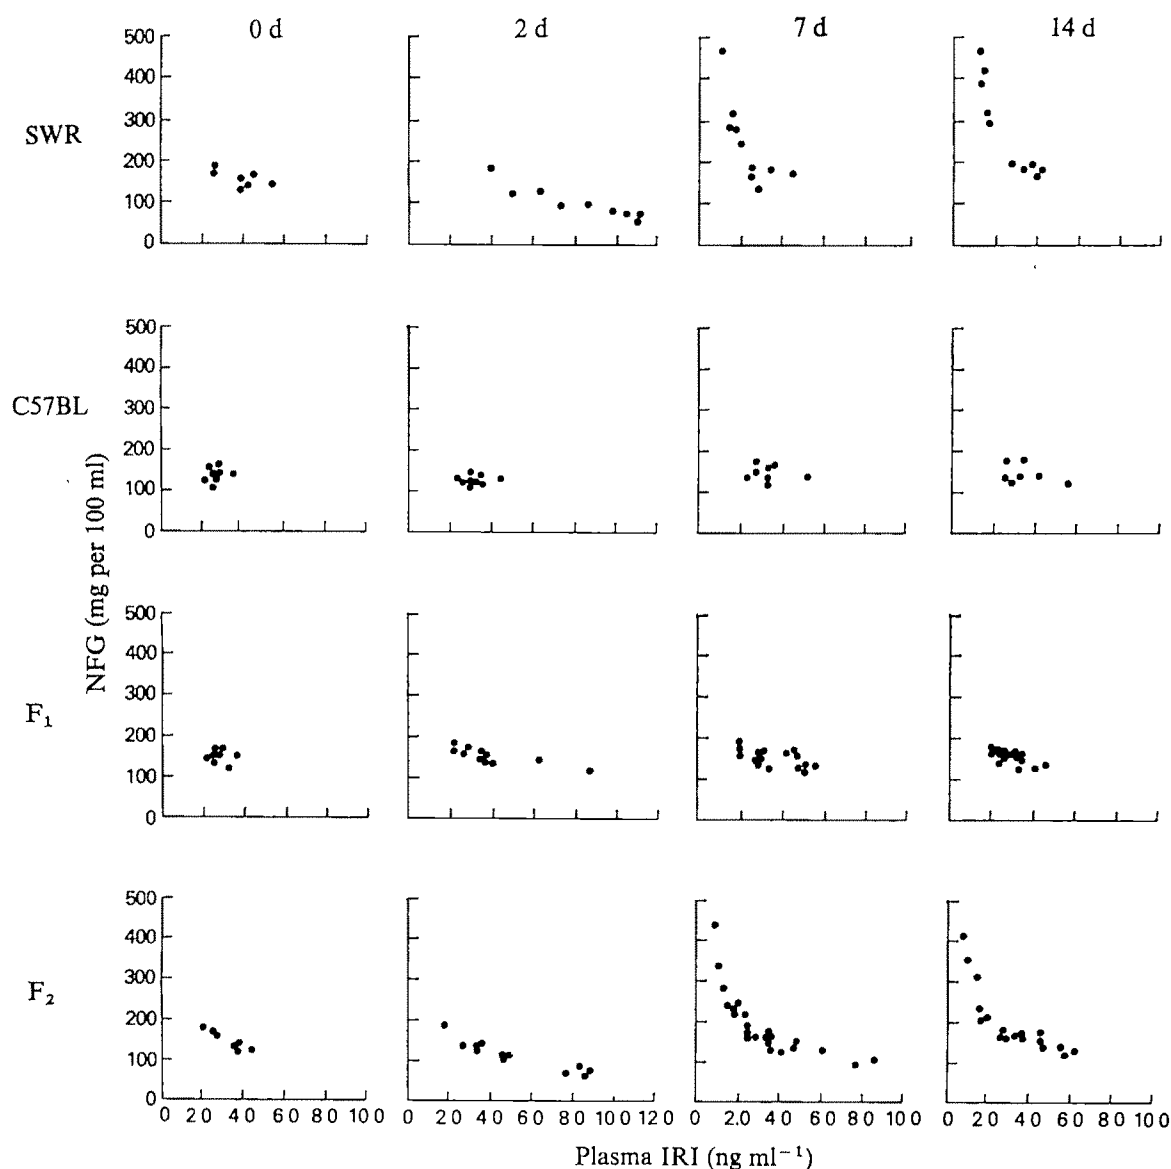

Fig. 1 Concentration of non-fasting glucose (NFG) and immunoreactive insulin (IRI) in the plasma of susceptible (SWR/J) and resistant (C57BL/6J) mice and their F_1 and F_2 offspring at different times after infection with EMC virus. Only male mice were tested and each point represents data from an individual animal.

occurred 48 h after infection and was more pronounced in males than females. At 48 h, up to 12 times more virus was recovered from β cells of SWR/J male mice ($2.6 \pm 2.8 \times 10^5$ PFUs) than C57BL/6J male mice ($2.1 \pm 0.7 \times 10^4$ PFUs), and analysis of variance revealed that the mean difference between the two groups was highly significant ($P < 0.005$). The mean virus titre in the β cells of the F_1 hybrids ($2.9 \pm 0.7 \times 10^4$ PFUs) was not significantly different from that of the resistant C57BL/6J mice ($P \geq 0.5$). The virus titre of individual F_2 animals, however, was spread out over a wider range and the standard deviation ($4.7 \pm 4.3 \times 10^4$ PFUs) was significantly different ($P < 0.005$) from that of the F_1 hybrids or the resistant C57BL/6J mice. The standard deviation of the F_2 females at 48 h also was significantly different ($P < 0.05$) from that of the female F_1 hybrids and the female C57BL/6J. Previous studies showed that male mice generally develop more severe hyperglycaemia than female mice after infection with EMC virus^{5,6}.

Figure 3 shows the relationship between viral titre and the levels of insulin and glucose in individual animals 48 h after infection. Although there were some exceptions, mice with the highest viral titre in the pancreas had the highest insulin and lowest glucose levels in the blood. Most of the SWR/J mice had viral titres

above 10^5 PFUs and their glucose and insulin values fell outside the normal range. In contrast, the resistant C57BL/6J and F_1 hybrid animals had viral titres below 10^5 PFUs and their glucose and insulin levels fell within the normal range. Animals in the F_2 generation segregated into two groups—the mice with viral titres above 10^5 PFUs had abnormal glucose and insulin values, while those with viral titres below 10^5 PFUs had glucose and insulin values within the normal range. Earlier studies had shown that the viral titres in the pancreas of susceptible mice was highest 2 d after infection and with the appearance of neutralising antibody at 3–4 d, the viral titre decreased^{5,7}.

We have shown that β cells from SWR/J mice are more susceptible to infection than β cells from C57BL/6J mice⁷. The experiments with individual mice reported here extend those observations, and show that the virus titre in β cells of F_1 hybrids was similar to that found in β cells of resistant C57BL/6J animals. Moreover, analysis of individual F_2 animals revealed two groups—one with viral titres approaching the susceptible SWR/J mice and the other with titres similar to that of the resistant C57BL/6J mice. Since the method of isolating β cells yielded preparations that were only about 85% pure⁷, the presence of virus

in the contaminating non- β -cell population might have obscured even greater differences in the actual viral titre in susceptible compared with resistant β cells. Nonetheless, our data show a correlation between viral replication and the subsequent development of clinical diabetes. Virus replicated best in β cells from SWR/J mice, and it was these animals that developed the most severe diabetes. Considerably less virus was found in β cells from C57BL/6J and F_1 hybrid mice, and these animals with high viral titres developed clinical diabetes. In contrast, the F_2 offspring segregated into groups with high and low viral titres; the animals with high viral titres were hyperinsulinaemic and hypoglycaemic at 2 d after infection due to acute β -cell damage and the rapid release of insulin. At about 7 d after infection these animals became hypoinsulinaemic and hyperglycaemic as a result of residual β -cell damage and the decrease in the insulin content of the pancreas^{1-4,7}. Because of the small size of the groups, the number of genes influencing susceptibility to virus-induced diabetes could not be analysed. Previous studies suggested that more than one gene was involved⁶.

Taken together, our studies suggest that EMC-induced hypoinsulinaemia and hyperglycaemia are secondary to genetically determined differences in the permissiveness of β cells to support viral replication. The demonstration of an association between particular HLA antigens (for example, B8 and BW15) and the frequency of juvenile diabetes supports the concept of a genetic predisposition to this disease¹⁰⁻¹⁴. The possibility that individuals

Fig. 2 Titre of virus in β cells from susceptible (SWR/J) and resistant (C57BL/6J) mice and their F_1 and F_2 offspring at different times after infection. Animals in the F_1 group represent both (SWR/J \times C57BL/6J) F_1 and (C57BL/6J \times SWR/J) F_1 . F_2 animals were bred from both (SWR/J \times C57BL/6J) F_1 and (C57BL/6J \times SWR/J) F_1 . Animals were infected intraperitoneally with 5.0×10^3 PFUs of EMC virus. The pancreas was removed, islets were collected and β cells were isolated by Ficoll density gradient centrifugation. The β cells were then homogenised and assayed for infectious virus on secondary mouse embryo cells. *a*, Male mice 24 h after infection; *b*, male mice 48 h after infection; *c*, male mice 72 h after infection; *d*, female mice 48 h after infection. Each point represents an individual animal and viral titre is expressed as PFUs per pancreas. Bars represent the geometric mean titre.

Activity of albumin conjugates of 5-fluorodeoxyuridine and cytosine arabinoside on poxviruses as a lysosomotropic approach to antiviral chemotherapy

THE therapeutic use of inhibitors of DNA synthesis as antiviral agents is hindered by their toxicity to dividing cells, which precludes the administration of effective doses. Consequently, although these drugs are very active in inhibiting virus replication *in vitro*, most of them are ineffective *in vivo*^{1,2}.

Albumin conjugates of two of these compounds, 5-fluorodeoxyuridine (FUdR)^{3,4} and cytosine arabinoside (ara-C) (G. B.-B. *et al.*, unpublished), release inhibiting substances in active form after penetration into the cells. This finding suggests a possible chemotherapeutic approach to attacking those DNA viruses which replicate in cells with a high protein uptake, that is, cells of the macrophage system⁵. After administration of such conjugates *in vivo* the inhibitors should be selectively concentrated in macrophages which are resistant to these drugs because they do not divide⁵. An attempt to concentrate in macrophages FUdR and ara-C by using their protein conjugates was suggested by the observation that the toxins amanitin and phalloidin after conjugation to albumin, change their original target selectively damage cells endowed with a high pinocytotic activity⁶⁻⁸.

Particularly suitable candidates to test this model of anti-

viral chemotherapy are poxviruses whose infectious cycle *in vivo* begins in macrophages⁹. We have studied the action of albumin conjugates of FUdR and ara-C: (1) on the replication *in vitro* of *Vaccinia* and *Ectromelia* viruses in cultures of L-929 cells and of mouse peritoneal macrophages; (2) on the growth of *Ectromelia* virus in mouse liver. *Ectromelia* virus, the agent of mousepox, is a poxvirus which, when injected intravenously into mice, is ingested mainly by the Kupffer cells in the liver where it starts replication. Then it infects neighbouring hepatic cells which in turn infect more hepatic cells after each cycle of growth. The resulting liver necrosis causes the death of mice^{11,12}.

Ectromelia virus (Hampstead mouse strain), grown in L-929 cells, was purified by zonal centrifugation in sucrose gradients according to Joklik¹³ and to Planterose *et al.*¹⁴ with slight modifications. The intravenous LD₅₀ of the purified virus for Swiss male mice of 28–30 g was 6.7×10^2 plaque forming units per g body weight. The *Vaccinia* virus used was from crude stocks produced in L-929 cells. The preparation of the FUdR-albumin conjugate (FUdR-RSA I) was carried out as described previously⁴ by coupling FUdR to crystalline rabbit serum albumin (RSA) by means of 1-ethyl-3-(dimethyl-aminopropyl)carbodiimide (EDCI) (Fluka). Ara-C-albumin conjugate (ara-C-RSA) was prepared by using the same concentration of reactants and by following the same procedure used for FUdR-RSA I. The molar ratios of FUdR and ara-C to RSA in the conjugates, determined in separate preparations by using ³H-FUdR and ³H-ara-C (Radiochemical Centre), were found to be 30 and 18 respectively. Sodium dodecyl sulphate (SDS)-polyacryla-

Cells were infected with *Ectromelia* or *Vaccinia* virus at the input multiplicity of 1 PFU per cell. Virus titres were determined by plaque counting in L-929 cells according to Blanden²¹ with an overlay medium containing 0.5% methylcellulose. Virus yields were obtained by subtracting the amount of virus adsorbed to cells from the virus titre at the end of the experiment. Mouse peritoneal macrophages were collected and cultured as described previously⁷. Experiments 1–4 were performed in L-929 cells, experiment 5 in mouse peritoneal macrophages.

*The amounts (μg) of inhibitors contained in the conjugates are shown in parentheses.

†Number in parentheses is the percentage of inhibition.

mide gel electrophoresis showed that only a small portion of the conjugates had a molecular weight corresponding to the monomeric form of albumin. The bulk of the conjugates was made up by molecular species corresponding to high molecular weight polymers of albumin which were formed in the presence of ECDI¹⁸. Since in ECDI conjugation stable covalent bonds are also formed between albumin and the urea derivative of carbodiimide¹⁸, RSA was allowed to interact with ECDI in the absence of FUDR or ara-C so that we could evaluate the possible antiviral activity of this complex (ECDI-RSA). We also studied the antiviral activity of another FUDR-RSA conjugate prepared by Dr de Vries in the laboratory of Professor Th. Wieland (Heidelberg). This conjugate (FUDR-RSA II) was obtained by coupling the hydroxysuccinimide ester of succinylated FUDR to RSA. This conjugation produces neither side reactions nor polymerisation of albumin¹⁶ and consequently avoids the heavy changes of protein molecules which follow carbodiimide coupling reactions. The molar ratio of FUDR to RSA in this conjugate was not known.

Table 1 shows that free and conjugated FUDR and ara-C inhibit the replication of *Ectromelia* and *Vaccinia* viruses *in vitro* after infection of L-929 cells or mouse peritoneal macrophages. *Ectromelia* virus yields in mouse peritoneal macrophages are lower than those in L-929 cells since virus replication is restricted in the former cells¹⁷. FUDR-RSA I and II are equally active *in vitro* on both viruses; ECDI-RSA has no effect. Thymidine and deoxycytidine, which are known respectively to remove totally or partially the effects of FUDR and ara-C¹⁸, counteract the antiviral activity of FUDR-RSA and of ara-C-RSA, indicating that the activity of the conjugates is due to the FUDR and ara-C moieties. Since albumin after penetration into the cells by endocytosis is broken down by lysosomal enzymes¹⁹, it is likely that the conjugates exert their antiviral activity after digestion of the protein moiety and release of the drugs, thus behaving as lysosomotropic agents^{20,21}. The assumption that the bonds linking FUDR and ara-C to RSA are broken after penetration of the conjugates into the cells is supported by the evidence that these bonds involve the primary hydroxyl

groups of FUDR and ara-C²² which must be phosphorylated so that the drugs can block DNA synthesis¹⁸.

The effects of FUDR-RSA and ara-C-RSA *in vivo* have been evaluated according to two criteria: (1) inhibition of virus production in liver; (2) survival time and number of survivors. The results of the experiments on virus production in mouse liver are given in Table 2. The compounds were injected intravenously. FUDR-RSA I, FUDR and ara-C were given at doses which, with the time schedule followed, corresponded to 1/3, 1/2 and 1/3 of the respective LD₅₀. Ara-C-RSA administered to normal mice with the schedule of experiment 3 but in doses three times higher did not kill any of the injected animals. Experiments 1-5 show that FUDR-RSA I and ara-C-RSA reduced significantly the virus yield in mouse liver whereas free FUDR and ara-C as well as ECDI-RSA were ineffective. Note that the active doses of the conjugates contained 19 and 15 times less FUDR and ara-C respectively compared with the amounts of free compounds used. FUDR-RSA II, which *in vitro* was as active as FUDR-RSA I was ineffective *in vitro* (experiment 4). The inactivity *in vivo* of FUDR-RSA II may depend on lack of aggregation and of profound protein changes, allowing the conjugate to escape a rapid uptake by macrophages²²⁻²³. In contrast, an aggregated and heavily modified albumin such as FUDR-RSA I is very quickly removed from the blood and taken up mainly by the Kupffer cells in the liver²²⁻²⁴. No reduction of virus titre by ara-C-RSA, determined in experiment 4, was found in the spleens. This result agrees with the observation that in mice the uptake of aggregated albumin is several times lower in spleen than in liver²⁵. Experiment 6 shows that ara-C-RSA is slightly active in reducing virus titre in the liver if its administration starts 12 h after infection, when the cycle of virus replication in Kupffer cells is completed^{11,12}. This finding demonstrates that the conjugates interfere mainly with the phase of virus infection which takes place in liver macrophages. This is supported by the results of experiment 7 showing that ara-C-RSA reduces the virus titre also if administered only within the first 12 h of infection. Table 3 shows the results of the survival experi-

Purified *Ectromelia* virus was injected intravenously into mice at the multiplicity of 2.4×10^6 PFU per g body weight corresponding to 360 times the LD₅₀. 48 h after infection livers were collected and homogenised in 5 ml of Hanks' balanced salt solution. Virus titres of clarified supernatants were determined in L-929 cells³¹. Five animals were used in each group. The results are given as the mean (\pm s.d.) of values obtained from livers of single animals, except in experiment 1 where livers from mice of each group were pooled before titration. The results were statistically evaluated by means of Student's *t* test and considered non significant (NS) when *P* was > 0.05.

*Doses are μ g g⁻¹ body weight; in parentheses, h after infection at which compounds were injected intravenously

Experiment 1: mice were injected intravenously with the same amount of virus used in the experiments of Table 2. Twelve animals were used in each group. The results were evaluated statistically by means of Student's *t* test.

Experiment 2: mice were injected intravenously with 5.4×10^8 PFUs per g body weight, equivalent to 8 times the LD₅₀. Number of survivors was determined 21 d after infection. The results were evaluated statistically by means of the χ^2 analysis.

*For explanation of doses see Table 2.

ments. When mice were challenged with an amount of virus equivalent to 360 times the LD₅₀, ara-C-RSA increased significantly the mean survival time, whereas FUDR-RSA I was inactive. Since FUDR-RSA I reduces the virus titre *in vivo* to the same extent as ara-C-RSA, the different effect of the two conjugates on survival time is probably due to higher toxicity of the former. When mice were infected with eight times the LD₅₀ a significantly higher number of survivors was observed in the groups treated with ara-C-RSA than in the control group. Ara-C-RSA was active only if administered during the period of virus replication in Kupffer cells. Free ara-C and ECDI-RSA were ineffective.

In conclusion, albumin conjugates of FUDR and ara-C inhibit the growth of *Ectromelia* virus in mouse liver whereas the free inhibitors are ineffective. The finding that ara-C-RSA exerts its antiviral activity in liver macrophages indicates that ara-C is concentrated in these cells following the injection of the conjugate, providing experimental support to the lysosomotropic approach of virus chemotherapy. This observation also suggests that these or similar conjugates could be effective not only on viruses but also on other intracellular microorganisms growing in liver macrophages. In future experiments we will try to concentrate FUDR and ara-C in hepatocytes by use of a conjugate obtained by coupling these drugs to desialylated fetuin which is taken up specifically by parenchymal liver cells^{27,28} where it is digested by lysosomal enzymes²⁷. Such a conjugate should inhibit the replication of *Ectromelia* virus in hepatocytes. This line of research could have implications in the treatment of other hepatic viral infections such as human hepatitis B, whose agent has been localised in hepatocytes²⁹ and has been found to be a DNA virus³⁰.

Experimental production of sheep pulmonary adenomatosis (Jaagsiekte)

SHEEP pulmonary adenomatosis (SPA) or Jaagsiekte is a contagious disease of unknown aetiology¹. A herpesvirus has been isolated from such tumours in Britain² and in Africa^{3,4} but attempts to produce adenomata with this virus have been unsuccessful (ref. 5 and W.B.M., G. Robinson, and K.W.A., in preparation). More recently, evidence has been presented that a type C virus with a density on a sucrose gradient of 1.5–1.20 g ml⁻¹, containing 60–70S RNA and RNA-directed DNA polymerase (reverse transcriptase) is present in the adenomatous tissue⁶. We wish to describe the production of SPA tumours in sheep experimentally infected with both agents.

Techniques⁷ similar to those of Perk *et al.*⁸, were used to confirm the presence of a reverse transcriptase-producing (RTP) agent in SPA tumour tissue from Scottish sheep. This enzyme was not detected in similar fractions from the lungs of unaffected sheep (Table 1).

A suspension of tumour from a natural case of SPA was subjected to equilibrium density centrifugation on a sucrose gradient. Fractions with densities of 1.15–1.17 g ml⁻¹ were centrifuged at 150,000g for 60 min at 4 °C and the pellet,

*Polymerase activity of 1.15–1.17 g ml⁻¹ fraction from sucrose density gradients of tumour or lung tissue suspensions, measured as increase in c.p.m. ³H-TTP incorporated into acid-insoluble material in 20 min using the methods outlined by Norval *et al.*⁷

‡Ratio of comparative activities are given in parentheses and the discriminatory effect of poly(A)-oligo(dT)₁₀ and actinomycin D on polymerase activity in the adenomata and healthy tissues are shown.

resuspended in 199 medium, was injected endobronchially into six Cheviot sheep. Herpesvirus isolated from an SPA tumour and passaged four times in embryo sheep kidney cells and once in sheep pulmonary macrophages (titre $\geq 10^{6.7}$ TCD₅₀ ml⁻¹) was similarly injected into four sheep. Both the herpesvirus and the density gradient fraction, containing the RTP agent, were injected into six more sheep. As controls, four sheep were given a supernate of tumour suspension and four, from the same flock, a supernatant prepared in an identical manner from apparently normal lung. To avoid cross infection, the groups of sheep were housed, as in previous transmission experiments, in separate loose boxes.

Results are shown in Table 2. One sheep, given the tumour supernatant, was clinically affected with SPA 6 months after inoculation. This diagnosis was confirmed histologically and all sheep were killed therefore 7–8 months after inoculation. A minimum of ten standard sites from the lungs of each sheep were examined histologically. In the group given the RTP agent alone, one sheep had two small (3–5-mm) adenomata and one other, histological evidence of adenomatous changes. Lesions in both sheep

Table 2 Evidence of pulmonary adenomata in the inoculated sheep

Material inoculated	No. in group	Macroscopic tumours	Histological adenomatous changes	Number with reverse transcriptase activity
Tumour supernatant	4	1	2	1
Herpesvirus and reverse transcriptase-producing agent	6	3	4	1
Reverse transcriptase-producing agent	6	1	2	0
Herpesvirus	6	0	0	0
Normal lung supernatant	4	0	0	0

Suspensions of finely minced tumour or lung tissue were prepared in Eagle's medium containing antibiotics and centrifuged at 12,000g for 30 min at 4 °C (inocula of "tumour or normal lung supernatant"). The supernate was recentrifuged at 120,000g for 90 min and the resulting pellet gently resuspended in 1 ml TNE buffer, layered on to a preformed gradient of 20–70% sucrose prepared in TNE buffer and centrifuged in a Beckman SW 40 rotor at 85,000g for 16 h at 4 °C. Fractions between densities of 1.15–1.17 g ml⁻¹ (the density of RNA tumour viruses) were pooled, diluted in TNE buffer and centrifuged at 150,000g for 60 min at 4 °C. The pellet obtained was suspended in 0.15 ml of TNE buffer and assayed for reverse transcriptase or further diluted for inoculation of sheep. Each inoculum was injected endobronchially in 8-ml volumes.

were minimal and present in four (13%) of a total of thirty-one sites examined. Of the sheep given both the RTP agent and the herpesvirus, three had definite macroscopic tumours and one was histologically positive (Fig. 1). No adenomatous lesions were found in any other sheep. All lungs were assayed for particles with reverse transcriptase activity and these were detected in lung tissue from two sheep (Table 2). Herpesvirus, which we have isolated from 24% of SPA tumours over the past 5 yr, was not recovered from any lung.

**Fig. 1** Focus of adenomatous change.

We can find no evidence to support the view that these tumours arose adventitiously or were caused by mycoplasma or other cultivable microorganisms. Since some sheep in both of the groups given the density fraction containing the RTP agent developed adenomatous lung lesions within 8 months of inoculation, it seems certain that this agent was involved in the production of these changes. Whether it alone is capable of initiating adenomatous changes or requires the assistance of the herpesvirus is conjectural and remains to be established. In the four affected sheep given both herpesvirus and RTP agent, lesions were extensive, and present in a mean of 63% of the areas of lung examined. This may indicate that the herpesvirus was involved in the production of these changes. The possibility that a small number of herpesvirus particles was present in the fraction containing the RTP agent cannot be dismissed completely and such contamination would simulate, to a lesser extent, the combined inoculum of herpesvirus and RTP agent. It may be that both viruses act synergistically to cause oncogenic transformation of the target cells, the type II alveolar cells or the cells of Clara in the bronchioles⁸, but the precise role of these viruses can only be elucidated by further experiments with purified virus.

Specific inhibition of mitochondrial Ca^{2+} transport by antibodies directed to the Ca^{2+} -binding glycoprotein

WE have described a glycoprotein isolated from various mitochondria¹, which binds Ca^{2+} with a dissociation constant of the same order of magnitude as the K_m for Ca^{2+} transport^{2,3}. This and other observations, including the effects of known Ca^{2+} transport inhibitors^{4,5} suggest that the protein is involved in the carrier mechanism for the transport of calcium in mitochondria. We have concluded that even passive efflux of Ca^{2+} from mitochondria requires the glycoprotein to be associated with the membrane⁶, and we consider this to be strong evidence that the passage of Ca^{2+} across the mitochondrial membrane requires the mediation of a transport system including the glycoprotein. We have sought to confirm these conclusions by immunological methods.

Rabbits were immunised using 2 mg of purified ox liver glycoprotein isolated in our laboratory as before⁷. Antigen plus Freund's complete adjuvant was given in five injections into all four legs and the neck. The operation was repeated with Freund's incomplete adjuvant a month later. A secondary immune response was evoked by intravenous injection of 0.2-0.5 mg of glycoprotein, and at weekly intervals 40 ml blood samples were taken from the marginal vein of the ear. The serum γ -globulin fraction was obtained by Keckwick's method⁸. Lipoproteins were removed by acidification with 0.05 M acetate buffer, pH 5.6.

Fig. 1 Elution pattern from Affi-Gel 10-glycoprotein column of γ -globulin fraction from rabbit serum. A sample of 4 mg of pure ox liver Ca^{2+} -binding glycoprotein taken up in 25 ml of 0.1 M bicarbonate-HCl buffer, pH 7, was added in 1 g of Affi-Gel 10 (BioRad). The mixture was stirred at 0 °C for 24 h. The resin was packed in a short column and washed free of 260 nm-absorbing material. 10 ml of 1 M ethanolamine was passed through the column and equilibration was carried out using 50 mM triethanolamine-HCl buffer, pH 7.8 containing 100 mM KCl. The sample was added in the same buffer.

Fig. 2 Immunodiffusion patterns of γ -globulin fractions before (a) and after (b) affinity chromatography on Affi-Gel 10. See text for explanation.

Preliminary experiments with γ -globulin fractions, derived from the same animal before and after immunisation with the glycoprotein, had shown that γ globulins could to some extent inhibit Ca^{2+} transport in rat liver mitoplasts (mitochondria devoid of the outer membrane). To avoid non-specific effects, we purified the specific antibodies by affinity chromatography (Fig. 1). Only a small portion of the total protein was retained on the column and was eluted only when the pH was shifted from 7.8 to 2.8 (500 mM formic acid-ammonium formate). Since the limiting factor in this experiment is the amount of antigen coupled to the resin, the whole procedure was repeated four times. The last passage on the column yielded only negligible amounts of specific antibodies. We calculated that the overall purification was of the order of 150 times. Starting from about 1.5 g of serum protein, 10 mg of purified antibodies was obtained. Figure 2 shows the immunodiffusion patterns obtained by Ouchterlony's method⁹ by testing the γ -globulin fraction before and after immunisation with the glycoprotein. The central well (Fig. 2a) contained the isolated glycoprotein, well (1) contained the γ -globulin fraction before immunisation and all the other wells (2-6) contained γ -globulins obtained from the animal after secondary immunoresponses had been evoked at approximately 20-d intervals. A single antibody class was present in all samples. As a control (Fig. 2b) proteins after complete absorption on a column of Affi-Gel were tested against the glycoprotein. They did not contain appreciable amounts of antibodies (wells (1), (3) and (5)). Immunoprecipitate was present in wells (2), (4) and (6), where the γ -globulin fraction had been placed before affinity chromatography.

Figure 3 shows the inhibitory activity of the purified antibodies on Ca^{2+} transport by mitoplasts and intact mitochondria. Ca^{2+} transport by mitoplasts showed a hyperbolic dependence on antibody concentration, as if the antibodies were titrating the specific sites freely accessible to them. As expected, on the other hand, mitochondria were much less sensitive to added antibodies, and decayed linearly as antibody concentration increased. Half inhibition was attained at approximately 1.5 μg antibody protein per mg protein with mitoplasts. The same effect was obtained in mitochondria with an antibody concentration about five times greater. It could be argued that antibodies against a mito-

Fig. 3 Effect of antibodies against the glycoprotein on Ca^{2+} transport in rat liver mitochondria and mitoplasts. Mitochondria and mitoplasts were prepared as before¹⁰; Ca^{2+} transport was followed by the murexide method¹¹ in a mixture containing in 3 ml: 5 mg mitochondria or mitoplast protein (Biuret reaction of Gornall *et al.*¹²), 100 μM murexide, 70 mM sucrose, 220 mM mannitol, 2 mM HEPES, pH 7.4, 5 mM acetate, 1 mM phosphate buffer, pH 7.4, 15 μM rotenone, 165 μM Ca^{2+} , 5 mM succinate. A 540–507 was recorded at room temperature with a Phoenix dual wavelength recording spectrophotometer. ○, Intact mitochondria; △, mitoplasts.

chondrial membrane component exert an inhibitory effect by inhibiting either electron transport or the energy conservation mechanism or both. Table 1 compares the effect of antibodies on Ca^{2+} transport, electron transport and respiratory control ratio in mitoplasts. Clearly low concentrations of antibody can block 45% of Ca^{2+} transport without effect on other mitochondrial activities. Even at higher concentrations the effect on electron transport and on respiratory control ratio was definitely lower than that on the movement of the cation.

These data indicate that specific blocking of the calcium-binding glycoprotein inhibits active Ca^{2+} transport. It is not surprising that the effect is much more evident in mitoplasts in view of the barrier present in intact mitochondria to the interaction between glycoprotein and antibody. On the other hand, intact mitochondria would be expected to be sensitive to the antibodies, in spite of the impermeability of the outer membrane to proteins. Preincubation for 1 h is necessary to obtain an almost complete combination between antigen and antibodies. During this time it is reasonable to assume that proteins could diffuse slowly across the outer mitochondrial membrane. This process has to be linearly correlated with the antibody concentration outside the mitochondria, which would explain the linear inhibition of Ca^{2+} transport in mitochondria. These data indicate that the mitochondrial calcium-binding glycoprotein is a necessary ingredient in mitochondrial Ca^{2+} transport.

Possible involvement of thiamine in acetylcholine release

ALTHOUGH it has long been thought that thiamine (vitamin B_1) and its phosphoric acid esters might be linked directly to excitation and propagation of nerve action potentials^{1,2}, the relationship has not been established firmly^{3,4}. We wish to report results which suggest that involvement with synaptic transmission rather than axonal conduction might explain why vitamin B_1 is required for nervous system activity. Experiments were performed on the electric organ of *Torpedo marmorata*, a richly innervated cholinergic tissue⁵. The results indicated that thiamine and its phosphoric esters are involved, either directly or indirectly, in the release of the neurotransmitter acetylcholine (ACh).

A first approach to the problem was made by comparing, in different conditions, ACh content with that of thiamine and thiamine phosphate esters of the electric organ (Table 1). Total thiamine content (thiamine plus esters) was found to range between 350 and 500 nmol g^{-1} of wet weight, with a rather large variation from one *Torpedo* to another. The relative distribution of thiamine, thiamine monophosphate (TMP) and thiamine diphosphate (TPP) was different in the following conditions. (1) When the tissue was incubated in physiological medium, most of the compound was found in the form of phosphate esters and the total content of ACh could be extracted without loss. (2) Homogenisation in the same medium before extraction resulted in significant hydrolysis of TPP into thiamine and a 45% loss of ACh; this part of the total transmitter destroyed by homogenisation is the fraction called "free ACh"⁶. (3) After incubation in a medium with high Mg^{2+} and low Ca^{2+} , which is known to block synaptic transmission, 33% of the esters were hydrolysed into thiamine and the amount of "free" ACh was decreased. (4) Continual stimulation of the electric organ at 5 per s, reported to induce sustained oscillations of the "free" ACh level^{7,8}, had the same effect on the phosphorylation of thiamine. In these preliminary experiments, however, the precise parameters of the thiamine oscillation were not established. We concluded that the level of "free" ACh in the electric organ was in some way related to the phosphorylation of thiamine.

In a second approach to the problem, electrophysiological and radiochemical methods were used to measure the effects of external thiamine and related compounds on synaptic transmissions. The first compound studied was oxythiamine, an analogue of thiamine known to inhibit the enzymes requiring TPP as cofactor but to have little or no effect on nerve excitation⁹. When added to the saline medium, oxythiamine caused considerable changes in the shape of single electrical discharges; both the amplitude and duration increased (Fig. 1). This was undoubtedly due to an increase in the amount of transmitter released, as demonstrated in radiochemical experiments (Fig. 2); samples treated with oxythiamine released more ACh than

Fig. 1 Effects of external thiamine, oxythiamine and adenosine on the electrical discharge. Pieces of tissue containing one to three prisms were excised from the electric organ and their response to single shocks were tested at long time intervals. The prisms are made of 400–500 superposed electroplaques and, when submitted to nerve or field stimulation, they generate an electrical discharge which is the sum of a large number of synchronised postjunctional potentials^{5,7,8}. When incubated in normal physiological medium, the tissue produced, for several hours, constant responses to single stimulations. The right hand upper tracings in the figure show discharges recorded before and after a 60-min incubation in 5×10^{-3} M thiamine (calibration: 0.2 V, 2 ms). Middle records: effect of 10^{-4} M oxythiamine for 45 min (0.5 V, 2 ms). The effect of oxythiamine was related to its concentrations in the 10^{-5} – 10^{-3} M range. Lower records: 5×10^{-3} M adenosine for 60 min (0.2 V, 2 ms). In the graph, the surfaces of the discharge are expressed as percentage of their initial values and plotted as a function of time; s.e. is indicated only for crucial points. Δ , 5×10^{-3} M thiamine; \square , 10^{-4} M oxythiamine; \circ , controls; \bullet , 10^{-2} M thiamine; \blacklozenge , 5×10^{-3} M adenosine.

the controls with the most striking difference observed during the first 2 min of continual stimulation.

The same methods were then used to study adenosine, which has been reported to reduce "quantal release" at the neuromuscular junction¹⁰. The effect of this compound, unlike that of oxythiamine, was to reduce the electrical discharge and decrease the quantity of ACh released (Figs 1 and 2). Addition of 10^{-3} M adenosine to the medium could reverse the effect of 10^{-4} M oxythiamine in 15 min.

Experiments in which 10^{-3} M TPP was added to the medium, showed that this ester had no effect on synaptic transmission, probably because of its inability to penetrate cell membranes⁴. The effects of thiamine itself were a function of concentration and time (Fig. 1). At a concentration of 10^{-2} M, thiamine first caused an increase in

Fig. 2 Release of radioactive ACh from pieces of the *Torpedo* electric organ. The tissue was incubated for 4 h in physiological medium in the presence of ^{14}C -acetate (—, 132 d.p.m. μmol^{-1}) and ^3H -choline (---, 1,320 d.p.m. μmol^{-1}) at the same concentrations (8.4 μM). In this tissue, the two precursors are incorporated into ACh^{14,15}. The fragments were washed overnight and then submitted to continual stimulation at 10 per s for 3 min during superfusion at 1 ml min^{-1} . ^{14}C and ^3H radioactivities were counted in the superfusing solution and provided a sensitive and direct measurement of the ACh released during stimulation. At rest, the level of radioactive choline was constantly less than that of acetate, but, on stimulation, they increased in a ratio of 1:1. Lower graphs, Effects of 10^{-4} M, oxythiamine, 10^{-3} M adenosine and 5×10^{-3} M thiamine after 1 h of incubation. Only the ^{14}C values are shown here because they were not significantly different from the ^3H values. The fine lines indicate controls. In the oxythiamine experiment, ^3H -acetate and ^{14}C -choline were used. Adenosine (5×10^{-3} M) had the same effects as 10^{-3} M. In the presence of adenosine, the electrical discharge started at a lower level than in controls, but it increased during stimulation, an effect already described for ATP in this tissue¹⁶. Thiamine (10^{-3} M) increased slightly, but not significantly, the amount of ACh released.

Table 1 Comparison between the phosphorylation of thiamine and the level of "free" ACh in the electrogenic tissue of *Torpedo* in different conditions

Extraction after	Thiamine (%)	TMP (%)	TPP (%)	"Free" ACh (nmol g^{-1})
Incubation in the physiological medium (11)	28.6 ± 2.5	28.6 ± 5.5	42.8 ± 5.2	296 ± 29
Homogenisation in the physiological medium (8)	46.1 ± 6	28 ± 8	26 ± 5.7	0
Incubation in the medium with 5.3 mM Mg^{2+} and 0.01 mM Ca^{2+} (4)	62 ± 15	4 ± 4	34 ± 13	58 ± 27

Pieces of electric organ were excised under Tricain anaesthesia and placed in a physiological medium suitable for elasmobranch fish⁶. Thiamine and its phosphoric esters were extracted with 5% trichloroacetic acid, separated by high voltage electrophoresis and their concentration was determined by the fluorimetric procedure of Itokawa and Cooper¹². ACh was measured in the same extracts by a radiochemical assay¹³. The values of thiamine, TMP and TPP are expressed as percentage (\pm s.e.) of the total content of thiamine plus esters; this total was 458 ± 92 nmol g^{-1} wet weight and did not show significant variations between the three conditions. "Free" ACh was determined as the difference between the total ACh (708 ± 64 nmol g^{-1}) and the ACh remaining after homogenisation of the tissue⁶. Thus "free" ACh was equal to zero by definition in the second condition. Numbers of experiments are given in parentheses.

the electrical discharge but, in a second phase, the discharge decreased considerably, the effects of thiamine thus becoming similar to that of adenosine. At a lower concentration (5×10^{-7} M) of thiamine, amplification of the discharge lasted longer but after 1 h transmitter release had already diminished (Figs 1 and 2). This apparent discrepancy is due to the thickness (4–6 mm) of the pieces of tissue, through which thiamine requires time to diffuse⁶, since it is from the surface of the samples that the transmitter is collected, but it is chiefly at the core of the tissue where the discharge is generated. The effect of thiamine in the first phase differed from that of oxythiamine in that it was essentially the amplitude of the electrical discharge that was increased rather than the duration. This effect was transient, however, for in a second phase, thiamine, particularly at a high concentration, caused a sharp reduction of the discharge, related to the decrease in the quantity of ACh released.

The rather unexpected electrophysiological changes observed in this study are unlikely to be due to modifications of the rate of ACh hydrolysis by acetylcholinesterase, for the inhibitors of this enzyme are known to alter nerve-electroplaque transmission in a different way⁷. This was confirmed in biochemical tests which revealed that oxythiamine and adenosine, at the given concentrations, had no effect on the activity of cholinesterase extracted from the electric organ. Thiamine was also found not to inhibit the rate of hydrolysis except at a concentration higher than that of the ACh used as substrate. This might be due to the capacity of thiamine to form complexes with ACh, which have been found to be increasingly stable as the proportion of thiamine is increased¹¹.

It can be concluded from the observations of endogenous thiamine and ACh release, that the presynaptic nerve endings are the most probable site of thiamine involvement in synaptic transmission. It seems, moreover, that thiamine might even be directly implicated in transmitter release. A possible mechanism to explain its role would be as follows: thiamine might, in some way, bind to a fraction of "free" ACh, the pool of transmitter available for release⁶⁻⁸. This fraction, under the influence of Ca^{2+} , would then be released in the synaptic cleft, perhaps in a quantal manner. The release would be accompanied by a transfer of phosphate either to or from the thiamine and might occur at the presynaptic membrane, possibly with the involvement of synaptic vesicles. External oxythiamine as well as thiamine in the first phase, would cause an increase in the fraction of transmitter loaded and released, whereas adenosine or an excess of thiamine would cause a decrease.

Further investigations are needed to establish the validity of this theory as well as to determine whether thiamine is also involved in the release of other transmitter substances. Our results, however, suggest that the requirement of the vitamin B₁ by the nervous system can be better explained by its involvement in synaptic transmission rather than in axonal conduction.

An inhibitory tripeptide from cat spinal cord

UNTIL quite recently, the possibility that naturally occurring peptides, with a few exceptions, such as substance P, might function to modify the excitability of neurones in the central nervous system (CNS) was considered rather remote. There is now increasing evidence to suggest that peptides have a greater range of actions and are more widely distributed than previously thought¹⁻⁶. In a search for physiologically active peptides in the CNS we have isolated a tripeptide from the dorsal columns of cat spinal cord, which has been partially characterised as His-(Gly, Lys). We have synthesised the two possible forms and tested their activity by iontophoretic application to single neurones in the spinal cord, the medial medulla oblongata and the dorsal column nuclei.

To extract peptides from central nervous tissue we used a technique which minimises degradative processes⁷. Lumbar segments L2–L5 of the spinal cord were exposed in barbiturate-anaesthetised cats and frozen *in situ* with liquid nitrogen. The frozen tissue was excised and allowed to thaw to 4 °C, when the dorsal columns were dissected out and homogenised in acetone: 1 M HCl (100:3 v/v) at –20 °C. The homogenate was stirred at 4 °C for 24 h. After centrifugation, the supernatant was lyophilised, suspended in a small volume of isopropanol–water (10:90 v/v), and applied to a Sephadex G-15 column. Peptides were detected in the column effluents by their absorption at 206 nm. One of the G-15 column fractions was run on a DEAE–Sephadex column to separate the peptides further and a fraction from this column was analysed by thin-layer chromatography.

Two separate methods were used to isolate individual peptides from this fraction. Dansylated peptides were chromatographed in two dimensions on polyamide plates; non-dansylated peptides were chromatographed on silica gel plates and located using fluorecamine. Fourteen components were detectable and one of them (that with the strongest fluorescence) had the R_f values shown in Table 1. This component, a discrete spot, was scraped from the polyamide plate. After hydrolysis, it was rerun on a second polyamide plate, when only dansyl-histidine could be detected, indicating that the N-terminal amino acid was histidine. The remainder of this second plate was eluted and dansylation of the concentrated eluate yielded only glycine and lysine on further chromatography. Since the elution time on Sephadex G-15 suggested a tripeptide structure, we concluded that the peptide was His-(Gly, Lys).

The two possible tripeptides His-Gly-Lys and His-Lys-Gly

Table 1 R_f values of the tripeptide His-(Gly, Lys) from cat spinal cord

	First dimension Solvent 1	Second dimension Solvent 2
Non-dansylated peptide (silica gel F254 plate)	0	47
Dansylated peptide (polyamide-6 plate)	Solvent 3 85	Solvent 4 5

The solvents were as follows: 1, butanol–acetic acid–water (4:1:1 by volume); 2, pyridine–acetic acid–water (10:6:3 by volume); 3, water–formic acid (200:3 v/v); 4, benzene–acetic acid (9:1 v/v).

Fig. 1 The effects of iontophoretically applied His-Gly-Lys and His-Lys-Gly on the firing rate, induced by a continuous current of 4 nA of L-glutamate, of a neurone in the dorsal horn of the lumbar spinal cord. Na^+ (20 nA) had no effect. Applications are indicated by the horizontal bars; currents are shown in nA. Ordinate: Mean firing rate in impulses s^{-1} in successive 5-s epochs. Solutions of the peptides were made up to 0.05 M, pH 4.1–4.5.

were synthesised by conventional methods by two different routes. Both utilised mixed anhydrides or azides for coupling but differed in the type of protective groups used. In one set of syntheses, the carboxyl terminus was protected with benzyl, the sidechain of Lys and the α -amino group of His with benzyloxycarbonyl. The alternative scheme utilised *tert*-butyl for the carboxyl terminus and *tert*-butyloxycarbonyl for the Lys side-chain and His α -amino group. After removal of the protective groups by hydrogenolysis or protonolysis, respectively, the free peptides were purified by ion-exchange chromatography on carboxymethyl cellulose to yield homogeneous materials as shown by thin-layer chromatography and electrophoresis in several systems. The products of all four syntheses contained the correct ratio of amino acids after both acid hydrolysis and digestion with aminopeptidase M, indicating absence of racemisation during synthesis. H-His-Lys-Gly-OH triacetate had $[\alpha]_D^{26} = -12.3^\circ$ ($C = 1$, water) whereas H-His-Gly-Lys-OH triacetate had $[\alpha]_D^{26} = +5.6^\circ$ ($C = 0.8$, water).

The two synthetic peptides and the endogenous peptide had identical R_f values in the thin-layer chromatographic systems used and the same elution time on the Sephadex G-15 column. Consequently, the amino acid sequence of the natural peptide could not be assigned by direct chromatographic comparison with synthetic samples and will have to await the isolation of further material. Nevertheless, the characterisation of the isolated peptide as His-(Gly, Lys) is supported by the identical chromatographic behaviour of the synthetic and naturally occurring compounds.

Both synthetic tripeptides were applied by iontophoresis to single neurones in three regions of the CNS in unanaesthetised, decerebrate, decerebellate cats (mid-collicular decerebration was performed under halothane anaesthesia). Since the natural peptide was extracted from the dorsal columns, the responses of neurones in the dorsal column nuclei were examined first, and this was followed by application to cells in the spinal cord and the medial brainstem. The peptides were tested for effects on spontaneous activity or, when this was low or absent, on activity induced by the continuous application of the excitant L-glutamate from another barrel of the micropipette.

The dorsal column nuclei were located from surface landmarks and neurones were identified by their localised ipsilateral receptive fields in response to hair movement or joint movement or touch. Of 24 cells tested with His-Gly-Lys, 21 (12 in the cuneate nucleus and nine in the gracile nucleus) were unaffected by currents up to 150 nA, whereas three neurones in the gracile nucleus were inhibited at currents from 50–100 nA. His-Lys-Gly was tested on 15 cells; one in the gracile nucleus was

inhibited and the remainder in both dorsal column nuclei showed no response.

In the spinal cord (L3–L5), the peptides affected a much larger proportion of neurones. When applied with currents of 10–50 nA His-Gly-Lys inhibited (Fig. 1) 17 (40%) of 42 neurones, the remainder being unaffected. The positions of four cells inhibited by His-Gly-Lys were marked with pontamine blue, and all of these were in the dorsal horn; three seemed to be in lamina V and one was at the border of laminae VI and VII. His-Lys-Gly was tested on six cells, two of which were inhibited.

To test the peptides on cells in the medial brainstem, micropipettes were inserted through the floor of the IVth ventricle between 1.0 and 4.8 mm rostral to the obex and 1.0–1.5 mm lateral to the midline. As in the spinal cord, both peptides had depressant effects on some cells. His-Gly-Lys inhibited 30 (52%) of 58 units and His-Lys-Gly 11 (37%) of 30 units. Some of these neurones were identified as reticular by their response to somatosensory stimulation over a large area of body surface.

In all three regions of the CNS the reduction in firing rate was rapid in onset, beginning within the first second of the ejection period and reaching a plateau within 15–20 s (Fig. 1). At the end of the application the firing rate returned rapidly to its previous level. The degree of inhibition was related to the strength of iontophoretic current, and clear responses were sometimes seen with currents as low as 10 nA. No excitatory effects were seen. In most cases when similar currents were used to eject the two compounds, His-Gly-Lys produced a greater degree of inhibition than His-Lys-Gly. In all, His-Gly-Lys inhibited 50 of the 124 units examined (40%) whereas His-Lys-Gly inhibited only 14 of 51 units (27%). The former thus seems to be more potent than the latter, although a more accurate comparison of potencies cannot be made without knowledge of the relative efflux rates of these substances from each micropipette, in relation to the current applied⁸.

The tripeptide His-(Gly, Lys) thus has inhibitory effects on some neurones in the dorsal horn of the spinal cord and in the medial brainstem, including the reticular formation. Although it was found in the lumbar dorsal columns it has little effect in the dorsal column nuclei, and since the ascending fibres to these nuclei are excitatory it is unlikely to be concerned in transmission in this system. The dorsal columns do, however contain other fibres, such as propriospinal and reticulospinal⁹, and the peptide may be associated with intersegmental fibres or descending fibres terminating in the dorsal horn. The occurrence of the tripeptide His-(Gly, Lys) in the spinal cord and its actions on selected neurones in the dorsal horn suggest that it may have a functional role in relation to neuronal inhibition in the spinal cord.

Di- and trimethylated congeners of 7-methylguanine in Sindbis virus mRNA

In the past two years it has become clear that most animal messenger RNA—both cellular¹⁻⁶ and viral⁷⁻¹¹—is "capped" by 7-methylguanosine (m⁷G) residues present in inverted nucleotide linkage at 5' termini of the general form m⁷G (5')pppNm. At least for certain mRNAs the capping m⁷G has an important role in mRNA-ribosome binding and thus in initiation of protein synthesis¹²⁻¹⁵. We now report novel forms of capped 5' termini on the main mRNA, '26S' RNA, coded for by the animal alphavirus, Sindbis. These termini contain, in addition to the usual m⁷G, its hypermodified congeners m₂^{2,7}G and m₃^{2,2,7}G. This last compound has been previously described only in small nuclear (sn) RNAs of unknown function^{16,17}, whereas m₂^{2,7}G has not been described previously.

Caps were obtained from methyl-³H-methionine-labelled 26S RNA, using T2-ribonuclease followed by DEAE-cellulose chromatography¹⁸. The recovered oligonucleotides were degraded to ribosides using bacterial alkaline phosphatase and snake venom phosphodiesterase¹; only the extreme 5'-terminal ribosides of such oligonucleotides were labelled, since 26S RNA lacks penultimate Nm residues¹⁸. Preliminary analyses indicated the presence of three methyl-labelled species: m⁷G plus two other ribosides whose properties suggested that they were also 7-methylated derivatives of guanosine, possibly m₂^{2,7}G and m₃^{2,2,7}G (data not shown). Accordingly, we prepared marker compounds by reacting m²G and m₂²G with dimethyl sulphate in conditions known to result in

preferential methylation at the 7 position^{16,19}. Evidence confirming that the products were indeed the expected m₂^{2,7}G and m₃^{2,2,7}G is provided by mass spectra of their free bases (Fig. 1). The most intense peak in the spectrum of both compounds is that of the molecular ion. The assignment of major peaks in Fig. 1a is: *m/e* 179, the molecular ion M; *m/e* 123, 95, 68, arising from the successive loss of cyanamide fragment (CH₃)HNCN, CO and HCN; *m/e* 150, possibly by the loss of CH₃N. The assignment of major peaks in Fig. 1b is: *m/e* 193, the molecular ion M; *m/e* 123, 95, 68, resulting from sequential expulsion of cyanamide fragment (CH₃)₂NCN, CO, and HCN; *m/e* 178, resulting from the loss of one methyl group; and *m/e* 164, possibly arising from expulsion of CH₃N. The loss of the methylamino group resembles that of *N*⁶-methylated and *N*⁶-dimethylated derivatives of adenine. The initial expulsion of a neutral cyanamide fragment with sequential elimination of CO and HCN is highly characteristic of methylated guanines²⁰. Below *m/e* 120, the mass spectra of both m₂^{2,7}Gua and m₃^{2,2,7}Gua are qualitatively similar to that of m⁷Gua (refs 20 and 21). For precise comparison with ³H-labelled samples from 26S RNA we also prepared ¹⁴C-methyl-labelled m₂^{2,7}G and m₃^{2,2,7}G in the same manner.

Figure 2 shows a phosphocellulose elution pattern obtained for the methylated ribosides of the 26S RNA cap, following the procedure used in the original isolation of m₃^{2,2,7}G (ref. 16). The two unknown peaks (I and II in Fig. 2) correspond precisely to the markers m₃^{2,2,7}G and m₂^{2,7}G, respectively. The third major ³H peak III corresponds, as expected, to m⁷G. The radioactivity in the void volume (V) probably represents partial degradation products of the relatively labile 7-methyl-purine ribosides^{16,23,24}.

Table 1 summarises the behaviour of m⁷G, m₂^{2,7}G, and m₃^{2,2,7}G, and their bases, in four other systems. In all cases the ³H from peaks I and II (Fig. 1), or the corresponding bases released by acid hydrolysis, ran with m₃^{2,2,7}G and m₂^{2,7}G, respectively, or their corresponding bases (these latter were the 'unidentified' bases in our initial report¹⁸ on acid hydrolysates of 26S RNA). We conclude that ribosides I and II are indeed m₃^{2,2,7}G and m₂^{2,7}G, respectively.

The m₃^{2,2,7}G residues of snRNAs U-1 and U-2 have been shown to occur as caps on the 5'-terminal sequence m₃^{2,2,7}G (5')pppAmUm . . . (refs 25 and 26), which resembles that of 26S RNA, mG (5')pppApUp . . . (ref. 27 and Dubin *et al.*, unpublished). Conceivably these two forms of RNA, although apparently grossly different in biological and chemical properties, are substrates for the same or related methylases. Another possibility suggested by the presence of similar caps

Fig. 1 Mass spectra of m₂^{2,7}Gua (a) and m₃^{2,2,7}Gua (b). Dried samples of ribosides prepared as described in the text were dissolved in 1 N HCl, heated for 45 min at 100 °C, adjusted to pH 8.5 with concentrated NH₄OH, and lyophilised to dryness. The mass spectral analysis was carried out at 70 eV using a direct inlet system at a temperature of 270 °C.

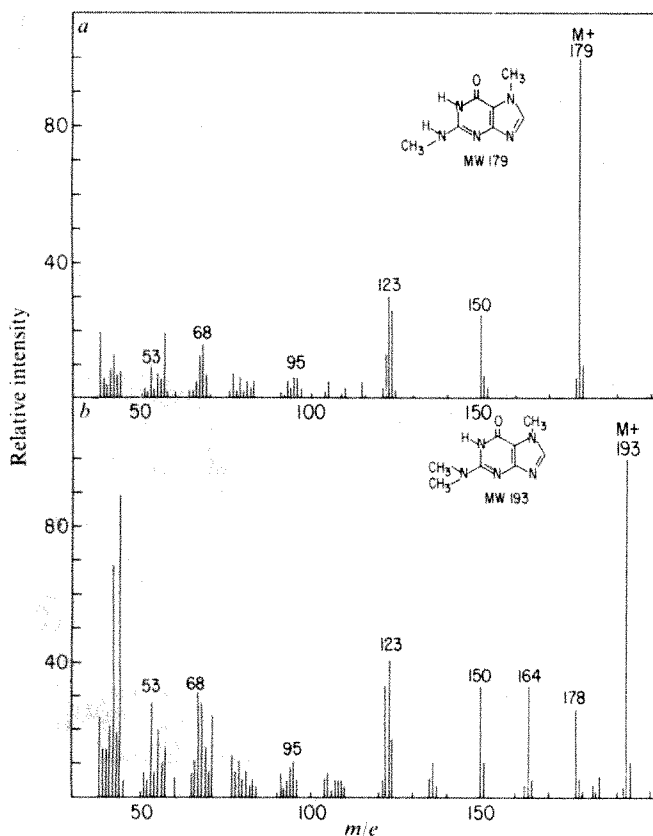

Table 1 Chromatography and electrophoresis of 7-methylated guanines and guanosines

	Mobility or <i>R_f</i> relative to adenine Electrophoresis, pH 3.5	Solvent system		
		A	B	C
m ⁷ G	1.18	1.25	0.15	0.54
m ₂ ^{2,7} G	1.18	2.06	0.45	0.89
m ₃ ^{2,2,7} G	1.18	1.85	0.89	1.33
m ⁷ Gua	0.50	0.85	0.57	—
m ₂ ^{2,7} Gua	0.55	1.93	1.06	—
m ₃ ^{2,2,7} Gua	0.73	1.70	1.12	—

Electrophoresis and chromatography were carried out as described previously^{1,18}. Chromatographic systems were: A, Whatman 3MM paper developed in isopropanol-11.6 N HCl-H₂O (60:17.6:22.4, by volume); B, Whatman 3MM paper developed in *n*-BuOH-H₂O (86:14, by volume in NH₃ atmosphere); C, thin-layer cellulose sheets developed in ethyl acetate-isopropanol-7.5 M NH₄OH-*n*-BuOH (3:2:2:1, by volume). For convenience we have expressed values relative to adenine, which is readily available and which moves well in all systems. *R_f* for adenine in systems A, B and C were about 0.29, 0.25 and 0.40; it ran about 20 cm towards the cathode in 3 h at 3,000 V. Abbreviations follow conventional usage (for example, m⁷Gua, 7-methylguanine; m⁷G, 7-methylguanosine).

Fig. 2 Phosphocellulose pattern of methylated ribosides from the Sindbis virus 26S RNA cap. The 5'-terminal oligonucleotide of methyl-³H-methionine-labelled Sindbis 26S RNA was prepared from infected chick cells and digested to its constituent ribosides as described previously^{1,18,22}. The digest was chromatographed on a phosphocellulose column using a linear gradient of 0.01–0.3 M ammonium acetate¹⁸. As markers we added ¹⁴C-methyl-labelled $m_3^{2,2,7}$ G and $m_3^{2,2,7}$ G and unlabelled m_7 G. Arrows indicate the midpoints of the 260-nm absorbancy peaks of the markers, and the arabic numeral next to each peak indicates the percentage of the endgroup ³H present in that peak. ○, ³H; ●, ¹⁴C.

on sn and 26S RNAs is that our hypermethylated congeners—or at least $m_3^{2,2,7}$ G—are not in 26S RNA proper but rather occur in snRNA–26S RNA complexes. We believe this is unlikely, since 26S RNA lacks the Nm groups that are abundant in snRNA; our infected cells were labelled in the presence of a level of actinomycin ($4 \mu\text{g ml}^{-1}$, ref. 18) that should substantially suppress cellular RNA synthesis; and recent studies (Dubin *et al.*, unpublished) indicate the presence of 1 mol m_7 G plus congeners per 26S RNA molecule.

There is at present no evidence for a biological role of the extra methyl groups of the 26S RNA capping residues. We are currently attempting to explore one obvious possibility—that they enhance affinity to ribosomes—by comparing poly-some-bound and free 26S RNA.

We thank C. Weston of Rutgers University for obtaining the mass spectra, V. Stollar and G. Guild for preparing 26S RNA samples, and H. Busch for providing a sample of $m_3^{2,2,7}$ G. This work was supported by the National Institute of General Medical Sciences, USPHS. C.-C.H.C. is a postdoctoral trainee under an Institutional National Research Award from the NCI, USPHS.

Distribution of inverted IS-length sequences in the *E. coli* K12 genome

THE genomes of *E. coli* and some of its plasmids contain a class of elements called insertion sequences (IS)^{1–5}. These elements exhibit various properties associated with modulation and alteration of gene expression. IS1 (length 800 nucleotide pairs^{2,3}) apparently plays a role in the amplification of resistance determinants in drug resistance factors^{5,6} and also causes polar insertion mutations^{2,3}. IS2 (length 1,400 nucleotide pairs²) behaves as a controlling element, which can turn gene expression on or off⁷. IS3 (length 1,400 nucleotide pairs³) has been associated with strong polar mutations, and is a constituent of a transposable drug resistance determinant⁸. IS2 and IS3 have also been shown to specify integration loci for the fertility plasmid F^{4,9,10}. Hybridisation data have allowed estimation of the number of IS1 and IS2 elements in the *E. coli* genome¹, but except for the region around *lac* and *purE*, little is known about their natural location in the genome.

While investigating the sequence organisation of three Hfr strains of *E. coli*, we encountered a number of intrastrand hybrid structures which provide information on the distribution of inverted sequences within the *E. coli* K12 genome. Figure 1

Fig. 1 Formation of intrastrand DNA hybrid structures. The upper portion of the figure depicts a slightly nicked DNA duplex. The letters each denote a block of nucleotides; the sequences complementary to each block are indicated by the corresponding primed letter. The sequence $r_1r_2r_3$ is repeated on the DNA molecule in inverted order. Random nicking of DNA duplex (or shear breakage of double-strand or single-strand DNA) produces some strands which have both the sequences $r_1r_2r_3$ and the complementary sequences $r_3'r_2'r_1'$, as indicated for the upper strand. After denaturation and the onset of annealing, the inverted repetitions on such strands can rapidly form intrastrand hybrids, since $r_1r_2r_3$ and $r_3'r_2'r_1'$ are physically linked. Other strands, like the lower one, contain breaks between the inverted sequences, and in such cases, the inverted repetitions will renature slowly since bimolecular processes are required. The intrastrand hybrid structure formed from the upper strand is shown at the bottom. The length of the duplex stem corresponds to the length of the inverted repetition, and the length of the single-strand loop indicates the spacing between inverted repeats.

shows that if a pair of sequences is present as an inverted repetition, denaturation and subsequent reannealing of the DNA may result in an intrastrand hybrid structure. The repeated sequences form a duplex stem whose length corresponds to the length of the repeated sequence. The DNA separating the inverted sequences appears as a single strand loop whose length corresponds to the distance separating the inverted repetitions. Directly repeated sequences will not form intrastrand duplexes. Figures 2 and 3 are electron micrographs of two different intrastrand hybrid structures obtained from the DNA of strain P804. Similar structures were seen with DNA extracted from the strains P4X and P3. In both figures, the length of the duplex stem is approximately 1,300 nucleotide pairs (1.3 kilobases, or kb).

Three size classes of single-strand loops were detected (Table 1). There were only two representatives of the largest size class. Intrastrand hybrid structures with larger loops were less abundant than structures with smaller loops. Since renaturation times were long, the difference in abundance of these intrastrand structures is unlikely to be the result of kinetic effects. Because DNA strand lengths for a typical preparation were 120 ± 60 kb, inverted repetitions separated by more than 180 kb could form loop structures only rarely. Inverted repetitions located far from each other are more likely to be separated by strand breaks between the inverted sequences than are closely linked inverted repetitions, and therefore larger loop sizes will appear less frequently than smaller ones, even though the more widely spaced inverted sequences may appear in the genome at the same frequency as the less widely spaced ones. This relative enrichment for smaller loop sizes is reflected in Table 1.

These experiments do not identify the DNA contained in the duplex stems; however, the stem sizes are approximately

Fig. 2 Intrastrand hybrid structure from *E. coli* K12 strain P804. Folded chromosomes were isolated by using modifications of the methods of Worcel and Burgi^{10,15}. Bacterial DNA was denatured by incubation in 0.33 M NaOH for 5 min at 37 °C, and then for 10 min at room temperature. The sample was neutralised and dialysed at room temperature for 2–3 h against 70% formamide, 0.25 M NaCl, 0.10 M Tris, 0.01 M EDTA, pH 8.5, for the reannealing step. The concentration of the bacterial DNA was approximately $1.5 \mu\text{g ml}^{-1}$. Renaturation was terminated by dialysis at 4 °C against 50% formamide, 0.10 M Tris, 0.01 M EDTA pH 8.5. DNA was mounted from 55% formamide by the basic protein film technique as previously described¹⁶. The arrow in the micrograph points to the duplex stem, whose length is 1.2 kb. The single-strand loop has a length of 29 kb. The scale bar indicates the distance corresponding to 1 kb (1,000 nucleotides of single-strand DNA or 1,000 nucleotide pairs of double-strand DNA). Circular reference molecules are from ϕX174 .

Fig. 3 Intrastrand hybrid structure from *E. coli* K12 strain P804. The stem (indicated by the arrow) has a length of 1.3 kb, and the loop has a length of 69 kb.

the same size as both IS2 and IS3. The duplex stem length associated with the 69-kb loops is 1.3 ± 0.1 kb, while the stem length for the 29-kb loop structure is 1.2 ± 0.2 kb. Histograms of stem lengths are shown in Fig. 4. The histogram for hybrid regions from the 29-kb structures (Fig. 4a) displays a shoulder corresponding to shortened stem lengths. Such shortening could result from partial melting of a partially mismatched structure, or it could indicate that the stems of the 29-kb loops are shorter and therefore different from the stems of the 69-kb loops.

Since the 0.8-kb IS1 element is known to be present in the *E. coli* genome¹, there is the possibility that intrastrand hybrid structures involving IS1 might form. Three intrastrand structures with duplex stems shorter than 1 kb (and distinct from the structures with 29-kb loops) were detected, but each displayed a different loop size. We would have detected any structure classes having hybrid portions in the 0.75–1.00-kb size range had they been present at frequencies comparable with those of the other structures. As Fig. 4a shows, a few examples of the 29-kb structure with duplex regions in this size range were seen, which confirms that our specimen scanning procedures were sensitive to this size range. We conclude that

Table 1 Distances separating 1.3-kb inverted repetitions in three strains of *E. coli* K12

Strain	Loop sizes (kb)		
	I	II	III
P3	29.4 ± 2.6 (11)	67.4 ± 3.8 (9)	184.7* (1)
P4X	29.5 ± 1.9 (6)	73.1 ± 4.1 (4)	—
P804	29.3 ± 1.4 (10)	69.6 ± 2.6 (5)	173.1 (1)
Average	29.4 ± 2.0	69.3 ± 4.1	

Intrastrand hybrid structures were detected by scanning denatured and reannealed preparations of *E. coli* DNA in the electron microscope. Sizes were calculated by using ϕX174 DNA mounted on the same grid as a size reference (taken to be 5.25 kb). The numbers of structures measured are given in parentheses.

*This structure contained two hybrid regions whose sizes and relative separation suggested the participation of sequences from the integrated F plasmid.

Fig. 4 Histograms of lengths of duplex hybrid regions for the major loop size classes: *a*, hybrid lengths associated with the 29.4-kb loop; *b*, hybrid lengths associated with the 69.3-kb loop.

there are probably few IS1 length inverted repetitions relatively close together in the strains which we have examined; however, we cannot rule out the possibility that our reannealing or mounting conditions are somehow unfavourable for formation or retention of such structures. It is important to note that inverted repetitions longer than 1.3 kb would have been detected if they were sufficiently close. No such structures were observed.

In addition to the inverted repeat structures described, more complicated examples containing two hybrid regions were seen, but these are attributable to participation of IS2 and IS3 elements present on the integrated F factor in these Hfr strains. It should be emphasised that the organisation of the integrated F in these three strains is known¹⁰ (our unpublished results), as are the structures of the added F and F-prime heteroduplex reference molecules which were present during these experiments. The structures which appear in Figs 2 and 3 are not characteristic of the F or F-prime reference DNA which was also present. The main size classes seen in strain P3 are found also in P4X and P804, even though the site of the integrated F factor in P3 is some 240 kb removed from the F integration site in P4X and P804. This provides further evidence that these inverted repeat structures are not dependent on the Hfr character of these strains.

The data presented here provide information on the distribution of IS2 and IS3 size inverted repetitions in the *E. coli*

K12 genome. Previous heteroduplex mapping of the F-prime F13, which carries the *lac-purE* region from *E. coli*, identified three IS3 elements and one IS2 in the region⁹. If these elements are normal constituents of *E. coli* K12, then the 69-kb loop is predictable from separation distances and orientations of IS3 elements in the *lac-purE* region. The location of the DNA contained in the smallest loop is unknown.

We can conclude that elements similar in structure and size to the *tet*^R transposon⁸ and the *kan-2* elements¹¹, which have flanking inverted repetitions of 1.4 kb, are absent in the strains which we have examined. The loop sizes which are seen in intrastrand hybrid structures containing these elements are in the 5–10-kb size range, and we would surely have detected them. Elements structurally similar to the TEM β -lactamase transposon TnA¹² would not have been detected in these experiments, since the short stems characteristic of their intrastrand hybrid structures would have looked like overlaps.

The Hfr strains P4X and P3 are closely related¹³, and they exhibit similar loop sizes. P804 is less closely related to P3 than is P4X¹³, yet the size classes correspond to those of P3 and P4X. This again suggests that these inverted elements are relatively stable components of the *E. coli* genome, as has been suggested for IS3¹⁴.

Cleavage map of colicin E1 plasmid

COLICIN E1 plasmid (colE1) is a closed circular DNA molecule with a molecular weight of 4.2×10^6 (ref. 1). ColE1 DNA has extensively been used as a molecular vehicle for cloning and amplification of DNA in genetic engineering^{2,3}. In order to expand such investigations, it is useful to make a cleavage map ordering colE1 DNA pieces produced by bacterial restriction endonucleases. *Escherichia coli* RI restriction endonuclease (R·EcoRI) has been shown to cleave colE1 DNA at a single unique site^{4–6}. We have now constructed a physical map with the EcoRI site as a reference point using two restriction endonucleases from *Haemophilus aegyptius* (R·HaeII and R·HaeIII). The map of the colE1 moiety involved in a hybrid plasmid pML21 (ref. 7) carrying about a half of the colE1 genome was also determined. Restriction endonucleases and fragments pro-

Fig. 1 Gel electrophoretic patterns of digests of colE1 DNA and the mini-colE1 segment of pML21 with restriction endonucleases. ColE1 DNA or the mini-colE1 segment of pML21 was digested with restriction endonucleases, electrophoresed on 5% and 10% polyacrylamide gels (0.6 cm × 12 cm), and the gels were stained with ethidium bromide (0.5 µg ml⁻¹). DNA bands were visualised in long-wave ultraviolet light and photographed using Kodak No. 23A red filter and Polaroid land pack film type 105. Photographs from 5% gels were shown above and those from 10% gels below. *a-e*, Digests of colE1 DNA; *f* and *g*, digests of the mini-colE1 segment of pML21. Restriction endonucleases used were: (*a*) R·HaeII, (*b*) R·HaeIII, (*c*) R·HaeII + R·HaeIII, (*d*) R·HaeII + R·EcoRI, (*e*) R·HaeIII + R·EcoRI, (*f*) R·HaeII, and (*g*) R·HaeIII. Capitals on the left side of *a*, *d* and *f* are HaeII fragments and those on *b*, *c*, *e* and *g* are HaeIII fragments, except "D" on *c*, that is the HaeII fragment. Roman numerals on the right side show the colE1 DNA fragments created by cleavages with two different enzymes. "X", "Y" and "Z" on *f* and *g* were the fragments found only in the digests of the mini-colE1 segment of pML21. Preparation of colE1 DNA, isolation of R·HaeII, R·HaeIII and R·EcoRI, digestion of DNA and method of polyacrylamide gel electrophoresis have been described⁹⁻¹². The mini-colE1 segment of pML21 was isolated from the EcoRI digest of pML21 DNA by Agarose gel electrophoresis¹².

duced by the cleavages were abbreviated as those by Smith and Nathans⁸. The size of each fragment was expressed as a percentage of the length of the colE1 DNA molecule.

ColE1 and pML21 DNAs were isolated respectively from *E. coli* P678-54 (colE1) and *E. coli* W3350thy-(pML21), as described earlier^{7,9}. R·HaeII and R·HaeIII were prepared from *H. aegyptius* by the method of Roberts *et al.* and R·EcoRI from *E. coli* RY13 by the method of Greene *et al.*¹². Restriction fragments were resolved by electrophoresis on either 5% or 10% polyacrylamide gel¹⁰ or on 1.2% Agarose gel¹², and visualised by staining with ethidium bromide. For isolation of fragments from gels, band regions visualised by a brief staining were homogenised in a few ml of 10 mM Tris-HCl (pH 7.6) and incubated for 15 h at 37 °C. The extract was concentrated and purified by passing through a Sephadex G-100 column (0.4 cm × 15 cm). The size of HaeII and HaeIII fragments was estimated from the distribution of ³²P in each fragment generated from uniformly labelled ³²P-DNA. The size of other fragments was estimated from the mobility relative to the HaeII and HaeIII fragments.

When colE1 DNA was subjected to complete digestion with R·HaeII, six specific fragments (HaeII-A to -F) were visualised after polyacrylamide gel electrophoresis and subsequent staining of the gels with ethidium bromide (Fig. 1*a*). On the basis of the relative yield of each fragment from uniformly labelled ³²P-DNA, their molecular weights were estimated to be 36.9%, 27.5%, 18.0%, 11.0%, 5.4% and 1.2%, respectively. The order of these fragments was determined from analysis of partial digests followed by redigestion of individual intermediate fragments. A representative electropherogram of partial digests

is presented in Fig. 2, in which several discrete fragments can be seen in addition to the limit digestion products. The approximate size of each band is given by the side of the gel column. DNA banding between HaeII-A and -D was completely digested with R·HaeII and the products were analysed. As a result, it was found that 6 out of 10 bands tested were intermediates of digestion (i1 to i6) and the others were HaeII fragments A, B, C and D. Each intermediate gave limit products as follows: i1 → B D, i2 → C D F, i3 → C E F, i4 → C E, i5 → C F, i6 → D F. By arranging these limit products in overlapping positions, the physical order of the HaeII fragments was deduced to be A E C F D B, with A and B being contiguous in the circular molecule. This order was further confirmed by analysis of the EcoRI site and the constituent HaeII fragments of pML21, as described below.

As one specific break is valuable as a reference point in the circular molecule, the location of the EcoRI cleavage site in the HaeII fragments was determined by comparison between the HaeII digests of the circular colE1 DNA molecule and the EcoRI-treated linear colE1 DNA molecule (EcoRI-A). The only difference in the two digests was the absence of HaeII-A among the EcoRI·HaeII products, and the appearance of two new fragments: one between HaeII-B and -C and the other between HaeII-C and -D (I and II in Fig. 1*d*). The EcoRI site was therefore within HaeII-A. This was confirmed by direct cleavage of HaeII-A with R·EcoRI (data not shown), the two products I and II being identified as EcoRI-A·HaeII-A1 and EcoRI-A·HaeII-A2, respectively. Their sizes were estimated to be 21.4% and 16.4%, respectively. Which end of HaeII-A is closer to the EcoRI site was determined with pML21 as follows.

Table 1 Digestion of purified *Hae* fragments with the second *Hae* enzyme

Original fragment	Products of the second digestion
<i>Hae</i> II-A	<i>HH</i> -II, <i>HH</i> -IV [†] , <i>Hae</i> III-B, <i>Hae</i> III-F
<i>Hae</i> II-B	<i>HH</i> -I, <i>HH</i> -V [†] , <i>Hae</i> III-C, <i>Hae</i> III-M*
<i>Hae</i> II-C	<i>HH</i> -III, <i>HH</i> -VII, <i>Hae</i> III-G, <i>Hae</i> III-I, <i>Hae</i> III-K, <i>Hae</i> III-L*
<i>Hae</i> II-E	<i>HH</i> -VI, <i>HH</i> -VIII, <i>Hae</i> III-N
<i>Hae</i> II-F	<i>HH</i> -IX [§] , <i>HH</i> -X [§]
<i>Hae</i> III-A	<i>HH</i> -I, <i>HH</i> -II
<i>Hae</i> III-D [†]	<i>HH</i> -V [†] , <i>HH</i> -X, <i>Hae</i> II-D
<i>Hae</i> III-E	<i>HH</i> -III, <i>HH</i> -VIII
<i>Hae</i> III-H [†]	<i>HH</i> -IV [†] , <i>HH</i> -VI
<i>Hae</i> III-J	<i>HH</i> -VII, <i>HH</i> -IX

Each *Hae*II and *Hae*III fragment shown in the first column was purified by polyacrylamide gel electrophoresis and completely digested with the second *Hae* enzyme. Limit products determined by gel electrophoresis are shown in the second column. In parallel experiments, *Hae*II-D, *Hae*III-B, *Hae*III-C, *Hae*III-F, *Hae*III-G and *Hae*III-I were confirmed to carry no *Hae* cleavage site inside.

*The sizes of *Hae*III-L and *Hae*III-M were about equal, one derived from *Hae*II-C was named *Hae*III-L.

†Digestion of *Hae*III-D and *Hae*III-H with R-*Hae*II was done in the presence of *Hae*III-C and *Hae*III-G, respectively.

‡*HH*-IV and *HH*-V were indistinguishable by gel electrophoresis; one derived from *Hae*II-A was named *HH*-IV. This *HH* fragment should be identical to the one produced from *Hae*III-H, because analysis of overlapping positions at the other end indicates that *Hae*II-A partly overlaps with *Hae*III-H but not with *Hae*III-D. Similarly, the other overlapping fragment produced from *Hae*II-B and *Hae*III-D was named *HH*-V.

§Although not directly demonstrated, *HH*-IX and *HH*-X are evidently derived from *Hae*II-F because the total length of these two fragments is comparable to that of *Hae*II-F and there is no other candidate yielding these fragments.

As previously described^{7,13}, this plasmid replicates as the *colE1* replicon, and yields two fragments when digested with R-*Eco*RI: the longer one contains kanamycin resistance marker but no *colE1* DNA, and the shorter one, defined as the mini-*colE1* segment, continuously carries 49% of the *colE1* genome and a small amount of non-*colE1* DNA sequence (about 5% length of *colE1* DNA). One end of the latter fragment is precisely homologous to one end of the linear *colE1* DNA generated by the cleavage with R-*Eco*RI. Therefore, pML21 should carry one of the two *Eco*RI-A-*Hae*II-A fragments of *colE1*. When the mini-*colE1* segment of pML21 was digested with R-*Hae*II, *Eco*RI-A-*Hae*II-A2 in addition to *Hae*II-C, -E, -F and a new fragment "X" were produced, but not *Eco*RI-A-*Hae*II-A1, *Hae*II-B and -D (compare Fig. 1d and f). The "X" fragment was interpreted to carry a part of *Hae*II-D and the non-*colE1* DNA in the mini-*colE1* segment of pML21 from its electrophoretic

mobility. It was thus concluded that *Eco*RI-A-*Hae*II-A2 was next to *Hae*II-E, confirming that the fragment linked to *Hae*II-E was *Hae*II-A but never *Hae*II-B.

Since use of different restriction endonuclease for fragment analyses at overlapping positions strengthens fidelity of the physical map, digestion of *colE1* DNA with another enzyme R-*Hae*III was performed. R-*Hae*III cleaved *colE1* DNA into 14 pieces (*Hae*III-A to -N in Fig. 1b), in which C and D, G and H, and L and M were respectively inseparable in the conditions used. The molecular weights for *Hae*III fragments (A to N) estimated as in the case of *Hae*II fragments were 17.3%, 16.6%, 14.3%, 14.3%, 6.9%, 6.7%, 6.5%, 6.5%, 4.0%, 2.7%, 1.2%, 1.1%, 1.1%, and 0.8%, respectively. Combined digestion of *colE1* DNA with R-*Hae*II and R-*Hae*III gave 20 pieces as expected from additivity of the number of cleavage sites (Fig. 1c). From comparison between the gel electropherograms of the digests of *colE1* DNA with both R-*Hae*II and R-*Hae*III and with either one, it is evident that 10 out of 20 fragments correspond to *Hae*II-D, *Hae*III-B, -C (or -D), -F, -G (or -H), -I, -K, -L, -M, and -N. This was confirmed by direct digestion of each fragment with the second *Hae* enzyme (see below). As the sizes of *Hae*III-C and -D, and *Hae*III-G and -H were about equal, the fragments carrying no *Hae*II cleavage site were named *Hae*III-C and -G, respectively. It was thus concluded that *Hae*II sites were present in *Hae*III-A, -D, -E, -H and -J, and that all *Hae*II fragments except *Hae*II-D contained *Hae*III substrate sites. The remaining 10 fragments, *Hae*II-*Hae*III-I to -X (designated as *HH*-I to -X), were produced by cleavages with *Hae*II at one end and with *Hae*III at the other end. Their sizes estimated from their electrophoretic mobilities were 9.1%, 8.6%, 5.3%, 3.3%, 3.3%, 2.9%, 1.7%, 1.6%, 0.9% and 0.4%, respectively. To analyse which *Hae*III fragments were contained in a particular *Hae*II fragment, and vice versa, and from which *Hae*II and *Hae*III fragments a particular *HH* fragment was derived, each *Hae*II and *Hae*III fragment except small fragments (that is *Hae*II-F and *Hae*III-K to -N) were purified and digested with the second enzyme, and the fragments produced were determined. The results are summarised in Table 1, from which we can deduce origins of all *HH* fragments and, therefore, relate the two sets of fragments as follows:

Fig. 2 A gel electrophoretic pattern of partial digests of *colE1* DNA with R-*Hae*II. *ColE1* DNA was partially digested with R-*Hae*II by reducing the amount of enzyme, and subjected to electrophoresis on a 5% polyacrylamide gel. Since no partial digestion product with electrophoretic mobility faster than that of *Hae*II-D was found in preliminary experiments, electrophoresis was done at about twice the current of that in Fig. 1 for obtaining good separation. Capitals indicate the band positions of *Hae*II fragments, and i1 to i6 are intermediate fragments of digestion. The approximate size of each band is given on the right-hand side. Since *Hae*II-A and i1, and *Hae*II-B and i2 were respectively too close to isolate, redigestion was performed on the mixture.

<i>Hae</i> II	A	B	D	F	C	E	A
<i>HH</i>	II	I	V	X IX VII	III VIII	VI IV	
<i>Hae</i> III	A	(C, M)	D	J	(G, I, K, L)	E	N H (B, F)

Fig. 3 Physical map of the colE1 genome constructed by the cleavages with R·EcoRI, R·HaeII and R·HaeIII. The inner and outer rings show HaeII and HaeIII fragments, respectively. The EcoRI cleavage site was designated the zero point, and each cleavage site was numbered in the clockwise direction (circled numbers). The map distance from the zero point is shown as the fraction of the length of colE1 DNA in the same direction. Heavy line indicates the region carried by pML21.

To determine the positions of HaeIII-B and -F in HaeII-A, the location of the EcoRI site in HaeIII fragments and the constituent HaeIII fragments of pML21 were analysed. The electropherogram of combined digests of colE1 DNA with R·EcoRI and R·HaeIII indicates that HaeIII-B was split with R·EcoRI into two fragments, EcoRI-A·HaeIII-B1 (11.4%) and EcoRI-A·HaeIII-B2 (5.9%) (I and II in Fig. 1e). Digestion of the mini-colE1 segment of pML21 with R·HaeIII yielded EcoRI-A·HaeIII-B2, HaeIII-E, -F, -G, -H, -I, -J, -K, -L, -N and two new fragments "Y" and "Z" (Fig. 1g). Thus it was concluded that EcoRI-A·HaeIII-B2 and HaeIII-F were within EcoRI-A·HaeII-A2. The appearance of the two new fragments indicates that non-colE1 DNA in the mini-colE1 segment of pML21 contains one HaeIII site.

We can usefully summarise all the foregoing data in a single cleavage map of the colE1 genome, incorporating the various cleavage sites and molecular weight estimates of the fragments (Fig. 3). The EcoRI site was designated the zero point and measurement of the map distance as the fraction of the length of colE1 DNA was made in the direction A B D F C E of HaeII fragments from this point. According to this expression, pML21 carries the region 0.51 to 1.0. Earlier work indicates that replication initiates at 18% distant from the EcoRI site and proceeds towards the distal EcoRI site⁴⁻⁶. The replication origin of colE1 is present in pML21 (ref. 7). Therefore, the origin and direction of DNA replication can be deduced to be 0.82 and anticlockwise on the map in Fig. 3.

We thank Dr K. Sugimoto for helpful discussion and a critical reading of the manuscript.

Corrigendum

In the article "Prehistoric exploration at Hadar, Ethiopia" by G. Corvinus (*Nature*, **261**, 571; 1976) no acknowledgement was given to the institution which funded the work. The author wishes to thank the Centre National de Recherche Scientifique for a grant in 1974 and for a fellowship in 1975.

Errata

In the article "Reactions involving singlet oxygen anion" by W. H. Koppenol (*Nature*, **262**, 420; 1976) for 'effects', page 420, paragraph 1, line 6, read 'involvement'. Also, page 421, line 29, insert 'quantitatively' between 'reacts' and 'with'.

In the article "New cranium of *Homo erectus* from Lake Ndutu, Tanzania" by R. J. Clarke (*Nature*, **262**, 485; 1976) the following corrections should be made. In the first paragraph on page 485 humanoid should read hominid. The semicolon in the third line of the second paragraph on page 486 should be replaced by a comma and the last word in the same line should be 'lacking'. The last sentence in the same paragraph should read 'In addition, there are the isolated right tympanic plate and both isolated petrous temporals'. There is no scale on Fig. 1: the distance from a to O is 12 cm.

In the article "RNA polymerase specificity and the control of growth" by A. Travers (*Nature*, **263**, 641; 1976) the following corrections should be made on page 643: Paragraph 3, the sentence beginning in line 16 should read '... addition of T7 DNA results in a reduction of T2 RNA synthesis and a stimulation ...'; and the sentence beginning in line 28 should read '... the relative competition of T2 RNA and rRNA synthesis is virtually independent of the nature of the competing template.'; and in paragraph 6, the second sentence should read 'In two instances where stable RNA synthesis is shut off *in vivo* ppGpp accumulation and T4 infection ...'.

Nature Index and Binders

The **Index** for 1975 is now available, price £2.25. Copies of the 1974 index are still on sale, price £3.00. **Binders** for the journal are also available at £7.00 for four (a year of *Nature* fits into four binders).

Postage is included in the above prices. **Orders** should be sent, accompanied by remittance to Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire, England.

Asymmetric degradation of DL-leucine with longitudinally polarised electrons

BONNER *et al.* reported that when DL-leucine was irradiated with natural, antiparallel, polarised electrons of 120 keV energy, D-leucine was decomposed to a greater extent than L-leucine: with unnatural, parallel, polarised electron irradiation, however, L-leucine was degraded to a greater extent¹.

The mechanism of this phenomenon is not known. The authors were unable to decide whether the asymmetric degradations was caused by the longitudinally polarised electrons themselves, or by their bremsstrahlung. I wish to point out that the degradations measured could not have been caused by the bremsstrahlung of the bombarding electrons.

The fact that $\Delta E = 29$ eV for three cases is remarkable and shows that the law of exponential decomposition is applicable in the analysis. The value of ΔE coincides with the same values in the case of bremsstrahlung irradiation³. The ΔE value is very reasonable, showing that there is no need to assume any chain-type reaction mechanism.

The values of relative difference in the decomposition rates ($2Z$) show a broader spread. This, and the large value of ΔE in experiment (2), can be understood by taking into account the remarks of Bonner *et al.*, that it was difficult to control many of the experimental parameters of the polarised electron source. Even so, I feel that the value $2Z \approx 10\%$ can be accepted. (The upper limit for the same quantity in the case of DL-alanine was $2Z \approx 0.1\%$ (ref. 4).)

The energy of the incoming electrons

$2Z \approx 10\%$. A mechanism based on the direct interaction of polarised electrons with the asymmetric molecules, which was first outlined in ref. 6 and needs to be worked out in detail, may provide an approach to the understanding of asymmetric degradation.

Table 1 Analysis of the asymmetric degradation of DL-leucine

Experiment	Irradiation nA h	Sample decomposition	Energy/decomposed molecule (eV)	$\frac{\epsilon_D - \epsilon_L}{\epsilon_0}$	Weighted average
(1)	331	52.9	29.3	0.189 ± 0.039	0.151 ± 0.024
(2)	498	50.9	55	0.129 ± 0.030	
(3)	795	73.9	29	0.085 ± 0.015	0.081 ± 0.012
(4)	860	75.6	29	0.074 ± 0.020	

Analysing the data given in Table 1, of ref. 1, I calculated the average energy spent by the electrons to decompose a single leucine molecule (ΔE) and the relative difference of the decomposition rates for L- and D-leucine ($2Z = (\epsilon_L - \epsilon_D)/\epsilon_0$). For this purpose the following simple equation was used (which assumes an exponential decomposition of the molecules under constant irradiation²)

$$\frac{N_L - N_D}{N_L + N_D} = PZ \ln \frac{1}{1-D} \quad (1)$$

where the left side is the relative difference in the number of remaining L and D molecules, that is, the enantiomeric selectivity ($\%L - \%D$) defined in ref. 1; P is the polarisation of the incoming electron beam (percentage excess in Table 1 of ref. 1); and D is the sample decomposition (percentage divided by 100). The thickness of the irradiated DL-leucine samples (~ 20 mg cm⁻²) was nearly equal to the range of the bombarding electrons.

The data are presented in Table 1.

is lost in the sample by ionisation and radiation; the latter is the bremsstrahlung.

The fraction of the incident energy which is converted into bremsstrahlung in a thick target is approximately⁵

$$I/E = 7ZE \times 10^{-4} \quad (2)$$

where Z is the atomic number of the bombarded material (~ 7) and E is the energy of electrons in MeV.

Even if the whole energy of the bremsstrahlung had been absorbed in the sample, less than 0.1% of the degraded molecules would have been decomposed by bremsstrahlung. If the low degree of polarisation of the low energy bremsstrahlung ($P \approx 10^{-3}$) and the very low upper limit for Z ($< 3 \times 10^{-3}$ according to the measurements in ref. 2) were also taken into account, the upper limit of the enantiomeric selectivity would be $\sim 10^{-6}\%$. It is not possible therefore to understand the great difference found by Bonner *et al.* if the asymmetric degradation is caused by bremsstrahlung. There is no known mechanism to explain the effect of

BONNER ET AL. REPLY—Keszthelyi calculates that the average energy spent by the electrons to decompose a single leucine molecule is about 29 eV, that less than 0.1% of the degradations were due to bremsstrahlung, and that therefore ionisation must have engendered > 99.9% of the degradation as well as (in some unspecified manner) the observed asymmetric effect. We wish to comment on Keszthelyi's interpretation¹ of our results.

Using the sample weight, percentage degradation and total coulombs used in our experiments², one readily calculates that more than 3,000 molecules of DL-leucine were decomposed for each impinging primary electron. If each leucine decomposition requires an average 29 eV (ref. 1), each primary 120-keV electron thus loses an average total of about 87 keV in decomposing the leucine substrate. The remaining 32 keV presumably is lost in decomposing the collodian binder and in the rather inefficient geometry of the leucine target. There are thus some 3,000 primary processes initiated by each incident chiral electron. If primary ionisation is the predominant chiral process, the chiral efficiency of each such event must on average approach 5% to explain the asymmetric effect observed. If, as is possible, the incident electron loses its chirality after fewer collisions, the chiral efficiency must be still greater. What mechanisms might permit this?

Keszthelyi is correct that < 0.1% of the chiral primary electron energy is available as bremsstrahlung, which would

be fully circularly polarised only at the low intensity³, high energy end of its spectrum⁴. Thus it would seem unlikely that circularly polarised bremsstrahlung alone could explain our asymmetric effect² (ignoring such unknown amplification mechanisms as might involve the crystal lattice). There is, however, an additional source of chiral electromagnetic radiation potentially available for asymmetric photolytic decomposition—circularly polarised phosphorescence or fluorescence radiation emitted by the chiral substrate after excitation by the chiral primary electrons⁵. Another alternative amplification mechanism might involve chiral secondary electrons of about 29 eV, liberated through ionisation of the chiral substrate molecules by chiral primary electrons. Such chiral secondary electrons should be quite abundant, that is, about 3,000 per initial chiral primary electron. Experiments which we hope may shed light on these questions are in progress.

Our work was supported in part by the Office of Naval Research, NASA and ERDA. We are grateful to Professor H. P. Noyes (Stanford Linear Accelerator Centre) for his contributions to our reply.

Fractures and movement in the Adelaide rift zone

FOLD patterns in the Adelaide geosyncline have been interpreted by Coward¹ as evidence of left-lateral shear between two Australian subplates, although the crustal shears have not been defined in detail. It has been implied further that left-lateral movement still exists in this region^{1,2}. Apparently, studies of earthquakes^{3,4} have not been taken into account in the analysis of the tectonics of South Australia, since these indicate that right-lateral shear occurs at present, and may have done so in the past.

The seismicity data quoted¹ contain few events⁵, and only show that seismic activity exists in the region of the rift zone. More recent data suggest that well-defined trends in activity occur², which may outline the main fracture zones in the crust (Fig. 1). From focal mechanisms⁴ and trends in energy release⁶, we propose the tectonic model shown in Fig. 2. This is modified from Stewart and Mount⁴, and may be further altered for the eastern and southern extensions of the rift zone. Present faulting varies from strike slip near Adelaide to dip slip in the area of the Flinders Ranges⁴ (Fig.

2), and is more complex than the simple shear model used to interpret folding¹. The lateral extent of the seismicity trends (Fig. 1) and focal depths³ suggest that the shear zones in Fig. 2 represent fractures extending to the lower crust, and possibly into the upper mantle. The proposed shear zone at the northern end of the rift zone coincides with a region of high conductivity in the deep crust and upper mantle⁷ (Fig. 2). Since such shear zones may be active over extended periods of geological time⁸, the boundaries defined in Fig. 2 may represent the major lines of weakness in the crust throughout the life of the geosyncline (that is, since the late Proterozoic). The shear zones in Fig. 2 are approximately parallel to the sinistral shear couple proposed by Coward¹.

of the Adelaide rift zone (Fig. 2) may be compatible with the north-south compressive stress observed in central Australia⁹.

Widespread diapirism in the northern section of the rift zone (Fig. 2) seems to have occurred in conditions of regional tension (T. J. Mount, personal communication). On the model of Fig. 2, this implies that right-lateral movement occurred between the subplates at the time of diapirism. The intrusion of Proterozoic carbonate material into the overlying cover rocks may have continued from the Upper Proterozoic at least into the Cambrian¹⁰. Thus although left-lateral movement may have occurred at various times in the past, this may not always have been the case, and is probably not so at present. Rather, the movement may be

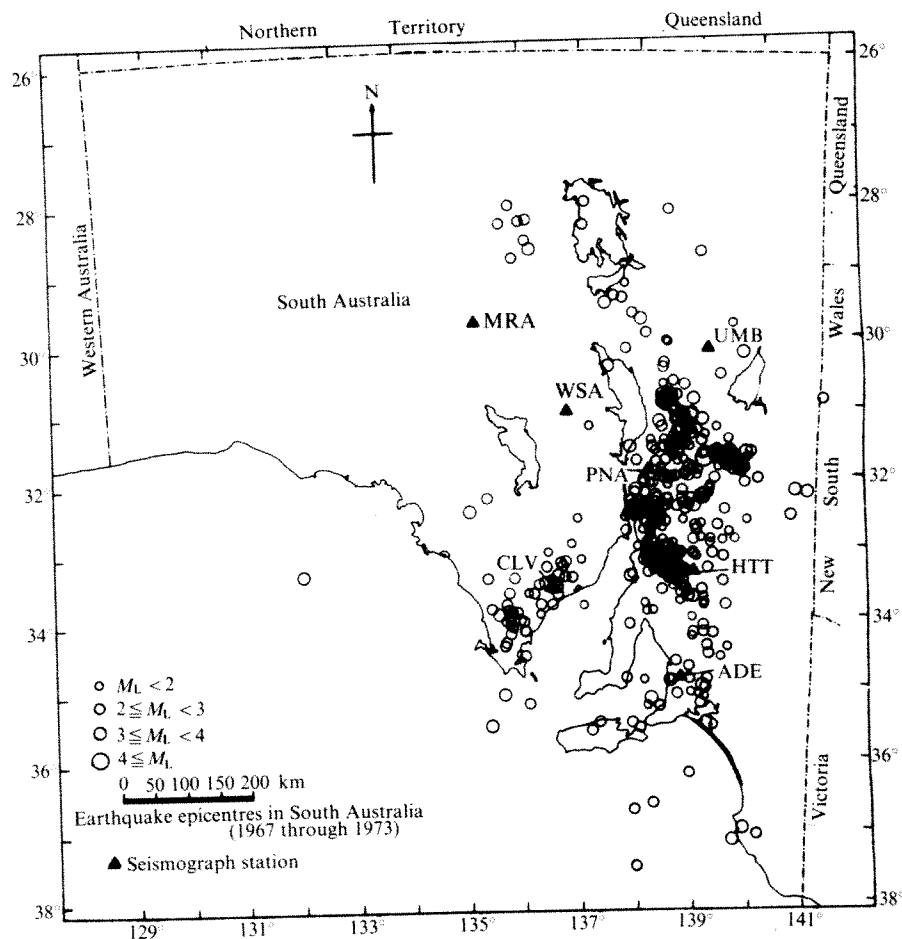

Fig. 1 South Australian seismicity, 1967–73.

Mechanism studies⁴ strongly suggest that right-lateral movement occurs between the eastern and western sections of the system, unlike the left-lateral shear originally proposed by Cleary and Simpson² and quoted by Coward¹. The right-lateral movement may continue southward along the transform fault to the mid-ocean ridge. This sense of motion on the north-western extension

oscillatory⁴, perhaps because of variations in plate velocity across Australia. The postulated left-lateral movement of 150 km (ref. 1) may be large in view of the remarkable uniformity of crustal thickness over much of the Adelaide Rift Zone¹¹. Although this may have been possible if faulting was almost pure strike-slip (as on the northwestern extension of the rift), smaller relative

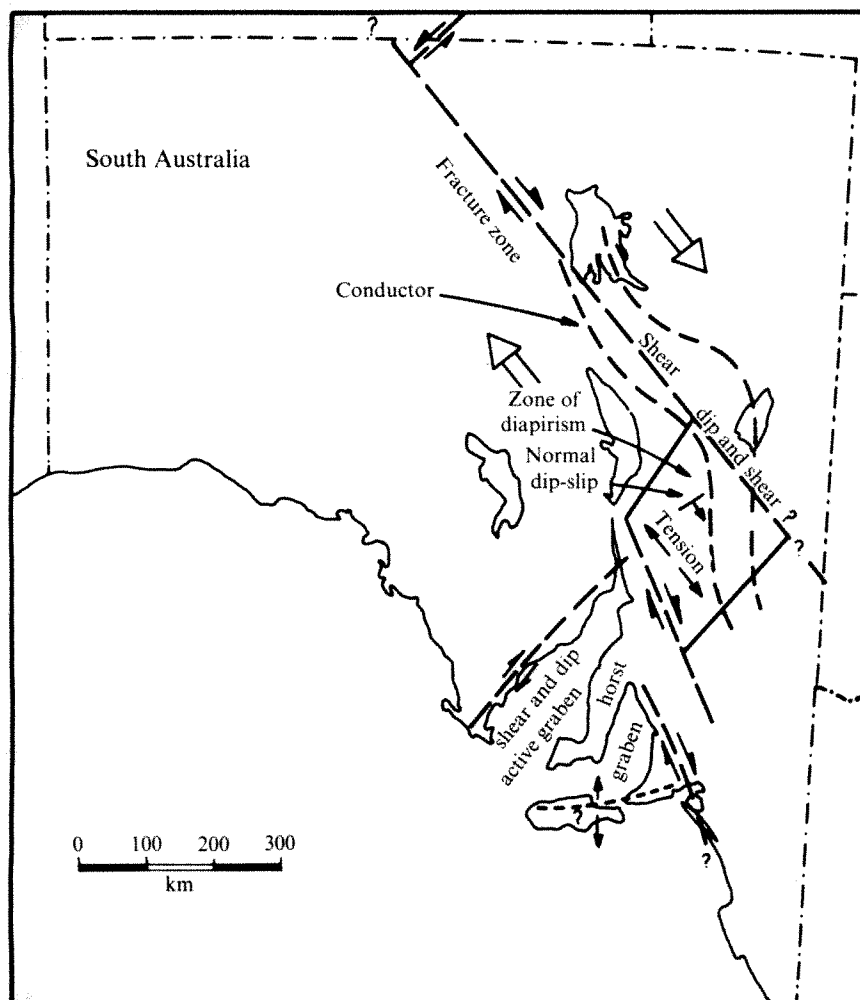

Fig. 2 Tectonic model for South Australia, showing the present sense of movement.

movements of only a few tens of kilometres may have been sufficient to produce vertical movements of several kilometres and much of the known geology of the region⁴.

Right-lateral shear may have been as important as left-lateral movement in the Adelaide Rift Zone, while dip-slip faulting may have been prominent in parts of the geosyncline. An interpretation of fold patterns should therefore allow for possible variations in the orientation, style and sense of faulting. The extent of shear movement across the whole system may also need revision.

Large scale Palaeozoic shear zone in Australia

HYPOTHESES invoking large scale horizontal displacements¹, fracture zones and the movement of plates², then ideas rejecting 'megashield'³, and now a revival of the large scale Palaeozoic shear zone concept⁴ have been generated to explain the pattern of geological structures observed in the Adelaide geosyncline of South Australia. The latest attempt⁴ has curiously ignored reference to earlier discussions¹⁻³ which I believe are strongly relevant to the basic argument of whether a Palaeozoic shear zone is a tenable hypothesis. It would seem that the whole spectrum of concepts has now been covered; sinistral movements⁴, dextral movements¹ and no relative movement³. Although Coward's case⁴ is rather difficult to assess, the idea seems to have appealed to Sutton⁵ who cited Coward's model as a possible example of deformation within continental plates.

Crawford and Campbell's model¹ supposed that, "The Adelaide geosyncline originally extended meridionally along the line of the present Flinders Ranges . . .", whereas on Coward's model⁴, "a regional pattern of folds on north-east-south-west axial planes was modified by a sinistral shear couple . . .".

Palaeomagnetic evidence from the Precambrian of South Australia was cited⁶ to disprove the extension of the Crawford-Campbell model to involve regions of the Gawler Block; this has since been acknowledged⁷. We made it quite clear, however, that the data obtained earlier from the southern part of the Adelaide geosyncline⁸ were inadequate (because of metamorphic effects), to permit comment on whether that region had suffered 'rotation' from shearing. The only region of the Adelaide geosyncline to yield acceptable palaeomagnetic data was the central region of the Flinders Ranges⁹. Those data, by comparison with late Precambrian-Ordovician data from Western Australia, central and northern Australia, are consistent with the principal axis of the geosyncline having maintained a meridional trend. The data are not consistent with originally north-east-south-west trending axial planes.

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

obituary

Keith Bullen came to Cambridge from New Zealand, and entered St. John's College in 1931. It was his great good fortune there to meet Harold Jeffreys, who was just embarking on a task which was to be momentous for the development of seismology. This was the construction of new travel-time tables for earthquake pulses, using sophisticated statistical techniques and taking full advantage of the data collected over several years in the International Seismological Summary. Jeffreys asked Bullen to assist him. In spite of the very irregular distribution of seismological stations over the Earth's surface and the inaccuracies of instruments at that time, the Jeffreys-Bullen Tables (1935 and 1940) have endured astonishingly, and are still in common use.

In 1936, using the distributions of seismic velocities with depth which were derived by inverting the travel times, Bullen obtained his first model of the distribution of density throughout the Earth—and for the rest of his life he was deeply involved in successive efforts to improve density models. He told the story of his work with skill and enthusiasm in his book *The Earth's Density*, which was published in 1975.

Bullen explored the density distribution in two ways. The seismic velocities alone are not sufficient to determine the two elastic constants and the density. One further physical assumption is

needed. In the series of models called *Bullen A* he used a relationship between pressure, density and compressibility following the method of Adams and Williamson, whereas in the series *Bullen B* he assumed that compressibility and the rate of change of compressibility with regard to pressure varied smoothly throughout most of the Earth's interior. The results of the two different methods were largely reconciled when satellite observations produced a significant correction in the accepted value of the Earth's moment of inertia.

After 1960, when observations of the periods of the free oscillations of the Earth became available, Earth models could be revised so as to fit these also. Bullen and Hadden produced a new series of models designed to do that, but Bullen noted that they had not been able to allow for the effect of anelasticity, which, as Jeffreys had pointed out, tended to lengthen the periods of free oscillations.

His experiences in trying to compare Earth models put forward by different workers convinced Bullen of the need for a single reference model with which all variants could be compared. He became Chairman of the Committee for a Standard Earth Model, sponsored by the I.U.G.G., and worked hard for it until ill health intervened.

Bullen wrote an *Introduction to Seismology* which is uneven in its demands on the reader, but has run

into three editions and is still found very valuable. He also wrote an excellent *Introduction to Dynamics*, now in its eighth edition. A great asset of the book is Bullen's effort to give the reader insight into the reasons which determine the next step to be taken, and to explain why certain methods succeed and others fail. Throughout the book one finds, under the heading S.P.I.C.E. (special point(s) in choosing examples) the type of helpful suggestions that a good tutor would make to a pupil.

Bullen was a brilliantly clear expositor, whether writing or lecturing. He was also a very effective and strong (sometimes obstinate) committee man, so that he was called to many positions of responsibility, especially on Australian scientific bodies and in the I.U.G.G. and the International Association of Seismology and Physics of the Earth's Interior. His outstanding contributions to seismology were widely appreciated, and many honours fell to him, including Fellowship of the Royal Society in 1949. He was awarded the Gold Medal of the Royal Astronomical Society, and medals of several Australian and American scientific societies.

Bullen was a man of great energy and resource, in spite of partial deafness throughout much of his working life; he travelled very widely. He died on September 23, 1976, aged 70, leaving colleagues and friends in every continent.

announcements

Meetings

November 19, **Magnetospheric Dynamics**, London (Royal Astronomical Society, Scientific Societies Lecture Theatre, 23 Savile Row, London W1, UK).

November 23–26, **Future of Aircraft All-Weather Forecasting**, London (The Manager, Conference Department, Institution of Electrical Engineers, Savoy Place, London WC2R 0BL, UK).

December 6–10, **Fall Meeting of the American Geophysical Union**, San Francisco (Meetings Registration, American Geophysical Union, 1909 K Street, N.W., Washington, D.C. 20006).

December 9–10, **Technologies for Rural Health**, London (The Executive Secretary, The Royal Society, 6 Carlton House Terrace, London SW1Y 5AG, UK).

March 30–April 1, **Mixing**, Cambridge (The Organising Secretary, 2nd Mixing Conference, BHRA Fluid Engineering, Cranfield, Bedford MK43 0AJ, UK).

September 13–15, **Particle Size Analysis**, Salford (Dr D. Dollimore, Department of Physical Chemistry, University of Salford, Salford M5 4WT, UK).

October 25–28, **Radar**, London (Deadline for abstracts: January 10) (IEE Conference Department, Savoy Place, London WC2R 0BL, UK).

November 22–24, 1977, **Design and Applications of EHV Substations**, London (Deadline for abstracts: November 29) (IEE Conference Department, Savoy Place, London WC2R 0BL, UK).

April 16–20, 1978, **Luminescence**, Salford (D. Irish, Pye Unicam Ltd., York Street, Cambridge CB1 2PX, UK).

September 4–7, 1978, **Medicinal Chemistry**, Brighton, Sussex (Symposium Secretariat, VIth International Symposium on Medicinal Chemistry, 31 Plane Tree Way, Woodstock, Oxford OX7 1PE, UK).

September 18–22, 1978, **Fat Research**, Brighton, Sussex (The Assistant Secretary, S.C.I., 14 Belgrave Square, London SW1X 8PS, UK).

November 18, 1976

Don't move!

FOR many years commissions, committees, working parties and individuals have pondered the problem of the scientific civil servant and his or her career prospects. In the last year or two much of this thinking has been fuelled by concern (at least by those on the outside) that the civil servant, with a generally securer job and an excellent pension scheme, has also been paid considerably better than his counterpart elsewhere. But long before this became an issue many thinking people, by no means all outsiders, were worried that the scientific civil service lacked either enough right openings for mature scientists or any means of goading such scientists not to sit and fester within the service. The Bondi Task Force which reported in 1974 was the most recent group to look at the problem, and came up with proposals to increase mobility into and out of the service.

A small unit was set up in the Civil Service Department in 1972, initially to work with the Bondi Task Force but eventually to proceed under its own steam in stimulating mobility. Unfortunately, its terms of reference were limited. Many believe that the best way to stimulate a scientist to give of his best and the best way to encourage an organisation to make the best use of its manpower is for the employer to make it quite clear to the employee at the outset that no one can be promised forty years of continuous satisfying employment. Under these circumstances there could be a valuable trade at all levels of people into and out of the civil service.

But this is not to be—and at times like the present, when projects are being trimmed or cancelled, note how the civil and public servants remain while industrial contractors have to cope with redundancies. The unit which was established was not given the job of helping people to make major switches in career; it was given the much more timid mission of stimulating two-year (typically) secondments into and out of the service—but with a guaranteed return ticket. And even this relatively unadventurous project has hardly met with waves of enthusiasm, as a recently circulated progress report of the Scientists Interchange Unit makes clear.

It is difficult to estimate exactly how many within the service might in one circumstance or another be candidates for secondment, or on the other hand how many

openings might arise which could be filled on a short-term basis by outsiders. But there are 2,300 Principal Scientific Officers in the service, and if we include other grades above and below this level and some in the analogous technical officer grades there might be 5,000 who should at least know about the scheme.

Yet in the last three years only 23 made an approach to the unit, and of these only five could be found places outside—four in industry, one in a research council. In the same period 20 secondments were made into the service—nine from industry, ten from universities and one from a research council. It is only fair to add that government departments sometimes arrange their own secondments without going through the unit, and in the same three years 18 did an outward move (though less than half into industry) and nine an inward move (two from industry).

The picture, as the unit admits, is disappointing. There seems little enthusiasm for tasting another job even with all the safety of one's own job being kept warm. It would be easy to conclude that the average British scientist is feeble-minded and unenterprising. That may indeed be true, but it should be made clear that the present scheme is actually a much more tricky one to make successful, and maybe a much less attractive one than a one-way ticket scheme. Skills have to be closely matched, employers have to be convinced that loss of employees for two years is in their interests, petty jealousies over salaries have to be overcome, temporary accommodation and schooling has to be found if a move is necessary, the briefing period may be a significant fraction of the total time available and so on.

Permanent moves could not be more difficult and indeed might be very much easier for all concerned. Certainly without them the same old accusations will continue to be thrown at the civil service, and scientists will have achieved little on their side to facilitate the more open style of government for which many yearn and which requires more flow into and out of government establishments. The Bondi Task Force should reconvene to consider, even in a time of gloomy economic prognostications, whether it cannot push for more than just secondments. □

Nuclear power, public interest and the professional

In the case of major and complex technological decisions in our time, such as that on nuclear power, it is sometimes said that the public is unable to make a full evaluation on its own and needs to trust some established professional and political mechanism instead. Jan M. Döderlein of the Institutt for Atomenergi, Norway, comments on the roles of the professionals and the nuclear critics.

NUCLEAR technology came to maturity at a time when attention was rightly focused more than before on the environmental aspects of industrial and energy production. As a result, in many countries nuclear stations are the only type of electric power plant for which detailed safety and environmental evaluations by government agencies are required, and where these evaluations are open to direct public participation. This has helped to create a public controversy over nuclear power, a controversy which appears in large measure to have spread from the United States. It presently focuses on three main topics: nuclear reactor accidents, the handling of radioactive waste, and the increased risks of proliferation of nuclear weapons (and therefore presumably of nuclear wars) from an expanding peaceful use of nuclear power.

Probably no technological decision in the history of mankind has been the subject of so many detailed studies, so much open discussion and such broad public participation. Amongst it all, some nuclear critics have given prominence to ethical aspects of the nuclear decision. This is justifiable to a certain extent since the application of nuclear power—indeed of any power—raises ethical questions. To carry this view to extremes in the way it is sometimes done, however, represents a vain attempt to set aside fundamental laws of nature and society.

One aspect of such ethical considerations is seldom if ever mentioned. The number of publications on astrology, on transcendental meditation, on nirvana and similar subjects is increasing sharply. Among the younger generations, and in some leading cultural and political groups, increasing numbers of people are seeking mystical or irrational escapes from many realities of modern society. There are thus clear indications that superstition, mysticism and emotionalism are on the upsurge.

Another symptom of this surge of emotionalism is the apparent tendency among sensitive and highly responsible citizens to shoulder the burden of guilt associated with the expansion of modern society. With some leading personalities in politics, industry and science, this burden is transformed into a desire to steer the development of

society away from perceived future cataclysms. Sometimes the bases for assuming such cataclysms are world models created by scientists. These provide some predictions of a near disastrous future for our society with the combined authority of science and leading personalities in society. Such an authority is merited neither by the quality of the world models nor by their basic assumptions.

One of the consequences of irrationalism and emotionalism is a desire for simplification of life and for a low energy society, a desire which is reinforced by "scientific" doomsday prophecies. Another is a strong sentiment against the people who are working for the application of technology within society, which erodes confidence in expertise. Nuclear power is not a simple technology; it can produce prodigious amounts of energy; emotionally it can be construed as having a certain "doomsday character"; and it requires qualified expertise. Nuclear power can therefore be seen as the antithesis of irrationalism, a view which easily creates a strong, emotionally based anti-nuclear attitude.

A natural outlet

The nuclear controversy is therefore a natural outlet for many irrational needs in our society, not least important of which are the irrational needs of many scientists, technologists and experts. These views are supported and broadened by fundamental observations made in another context by the epistemologist Karl Popper. He stated that, when threatened,

"the rationalist attitude to social and economic questions could hardly resist when historicist prophecy and oracular irrationalism made a frontal attack on it. This is why the conflict between rationalism and irrationalism has become the most important intellectual and perhaps even moral issue of our time".

One perspective on the nuclear debate, then, is that our dominant problem may be that of fighting emotionalism and irrationalism. This is not to use the words "irrational" and "emotional" in any derogatory sense. The fight is not against emotions or the irrational. The issue is the application of irrationalism and emotionalism in attacking major problems of our real, physical world.

The emotional and ethical aspects of nuclear power are trumpeted particularly by two groups of critics having the common denominator of emotionalism. One group consists of people for whom nuclear power is a vehicle of self-realisation. They play out some of their inner and emotional needs by taking an active part in the nuclear controversy, and the factual nuclear issues seem to play a secondary role. The other emotional group of nuclear critics is composed of professional and amateur politicians, notably leftist groups, anarchists, some populists and some environmentalists. Nuclear questions, real or imagined, are a means by which they further their own political goals, sometimes clandestinely, sometimes openly. A very different group of critics, the opportunists and malcontents, is cynically achieving fame and prominence by going into the nuclear debate, writing in the newspapers, giving lectures, going on television and so on. Needless to say, similar people are also found in the so-called nuclear community.

Characteristic shared

All three groups of nuclear critics share one characteristic: they seem to accept authoritarianism as a road to knowledge, often to the exclusion of other sources of knowledge. They rarely support their assertions with reasoned arguments or with facts, and they consistently invoke the opinions of some distinguished scientists, some Nobel-prize winners or some professional societies, ignoring others who disagree with their views. By confusing technical facts which can never be argued qualitatively, with value-judgments which can always be argued, the critics have in some countries succeeded in misleading sections of the public, causing them to believe that everything is open to argument and that the experts are confused. The truth is that the experts are not confused in their own field of expertise. Outside their own field they are not experts.

In the past two years we have seen a plethora of manifestos and statements for or against nuclear power by Nobel prize winners, by groups of scientists and by various professional societies. In connection with the statements, the eminent or special qualifications of the participants are always emphasised. While possibly not without merit, such statements should be viewed very critically. Practically without exception the participants in the anti-nuclear manifestos have no technical background in fields relevant to nuclear technology. Against the participants in pro-nuclear

manifestos, this criticism is less relevant.

One criticism is valid against all manifestos on nuclear power. The scale and timing of the introduction of nuclear power is a major and complex decision, resting on technical, economical, political and other social considerations. In a democratic society such decisions are not left to technological experts but to elected political officials. A professional using his specialist background in support of personal views on social questions tries to carry his professional authority over into fields where he should no longer have such authority, into fields where his opinions should be weighted on the "one man, one vote" principle.

Members of some professions believe they have more specialised knowledge, and that their political conclusions are based on sounder analysis of the evidence than the public. If one expects the public to have confidence in the role of professionals in decisions, the opinions of highly regarded experts within their chosen profession must be accorded a certain authority. But it is equally important not to support a carry-over of professional authority to political and ethical questions, a carry-over which may indicate a certain intellectual arrogance.

Assessing the 'facts'

Many "facts" in the nuclear controversy are to all appearances hotly contested. Some of these "facts" are not really facts, and deserve to be independently and critically evaluated by professionals and non-professionals alike. Among such "facts" in the nuclear debate are some aspects concerning the long term effects of radioactive waste, and the possible connections between nuclear power and proliferation of nuclear weapons.

Among the often repeated and confusing statements on radioactive waste are the suggestions that in this waste man produces materials that (uniquely) remain toxic for times much longer than we have had experience with, and that in nuclear reactors we have created materials that have never existed before.

Certain elements created in substantial quantities by nuclear power, for example plutonium (but not waste proper), remain toxic for times longer than the period of human civilisation. No industrial scale method for disposing permanently of radioactive waste is in use today. Deciding on appropriate handling of this waste is an important and difficult question which many countries are addressing. At a pilot plant level, however, there are solutions to the *technological* problems. Moreover the long life of

radioactive waste should not be judged in isolation; industry including power production from oil and coal gives uncontrolled releases to the environment of substances which remain toxic for infinite times; civilisation is accustomed to living with poisonous materials that remain toxic for times longer than the life of radioactive substances. For civilisation as we know it there is thus only a choice of *which* toxic materials we wish to handle.

With nuclear power man has not created any materials new to earth. Specifically, fission products and plutonium are naturally occurring elements, albeit in small concentrations. The ethical objection to nuclear power sometimes made on the basis of creation of "new" elements therefore has no foundation in fact.

The question of a possible connection between nuclear power and proliferation of nuclear weapons really has two separate aspects: one concerning sub-national groups using atomic explosives for terrorist purposes, the other concerning a possible increase in the number of sovereign nations with access to nuclear weapons. The understandable but unfortunate preoccupation of the mass media and the public with the matter of nuclear terrorism is distracting our attention from the far more important question of possible proliferation of atomic weapons beyond the present weapons states.

It is misleading to ask whether the spread of nuclear power inevitably leads to the spread of nuclear weapons. The peaceful uses of nuclear technology are now widespread; there are substantial quantities of peaceful and military fissile materials. The relevant question is whether a halt to the expansion of nuclear power, or to all use of nuclear power, will substantially reduce the potential for wars and the risk to the public from wars. Clearly it would not be meaningful to curtail the use of nuclear power for this reason without at the same time dismantling the many smaller reactors used for medical purposes, isotope production and research in most countries of the world. This aspect takes on added importance when one considers the substantially more complex operations required for using a power station rather than a small reactor for plutonium production.

Technological developments are likely to complicate further our questions about weapons proliferation. Within a few years there will be available, worldwide, several new techniques for enriching uranium. All of those being researched today are potentially simpler technologically than the present diffusion technique, and all of them can more easily be applied on a small scale. Ensuring peaceful uses

only of these techniques may be of more importance than the question of plutonium safeguards.

Unfortunately, nuclear proliferation is only part of a more fundamental and more serious contemporary question: can anything short of actual war stop a determined sovereign nation from getting primitive but usable versions of any kind of contemporary weapons technology—nuclear, bacterial, chemical or any other? Be that as it may, broad agreement could probably be obtained to curtail development of nuclear power if rational arguments could support an assertion that stopping peaceful uses of nuclear energy would reduce, if only marginally, the risk to the public from war and acts of terrorism. But reasonable, rational and valid arguments to this effect have not been put forward so far.

Reducing the risks

On this basis, expending efforts to stop the use of nuclear power does not seem to be a credible and useful way of reducing the risks of nuclear wars. Our most responsible and efficient attack on the nuclear proliferation problem would seem to be to channel our efforts into support for the UN and the nuclear supplier nations in their non-proliferation efforts; into the expansion of international safeguards inspection, including inspection of arrangements to protect physically all fissile material; into support for all practicable means of making the time span and the effort involved in converting in-reactor plutonium production to a workable nuclear weapon as large as possible; and last but not least into the problems created by the availability of new uranium enrichment techniques.

All human actions entail some unforeseeable consequences. Plans for action cannot be based solely on factual proofs and logical deductions; they must finally rest on political decisions made in the face of uncertainty, a point which gives a perspective on the place of technological facts in a world of values and emotions. Clearly, a number of irrational, emotional and ethical factors may be and should be of importance in a choice of power plants for the production of electricity. But an evaluation of *rational* and *quantifiable* factors tells us how many lives, which environmental improvements and what economic advantages we have to sacrifice in order to satisfy such emotional demands. In defining the role of the professional and in protecting the public interest, the importance of emotional factors in the nuclear controversy must be admitted; but as many problems as possible should be decided on a reasoned, factual and rational basis. □

No university without research

Gillian Boucher looks at how the Open University copes with the problem of conducting research

IT would be a forgivable mistake for anyone outside Britain's Open University to imagine that its sole function was to provide a university education by post: virtually all publicity has concentrated on its innovative and immensely popular courses. Even within the university it has sometimes been difficult to remember that there could be any aim in life beyond producing the next course unit. But the Open University's charter is utterly normal in allowing and requiring staff to undertake research, and recently, with the worst of the growing pains over, there has been a reassertion of the vital need for research to take its proper place alongside teaching.

Of course this view has always existed: most open university lecturers like research too much to forego it willingly and believe that an institution that simply packages information does not deserve to be called a university. But initially many people just did not have time for research. There are some who have gravitated towards the Open University because they get more satisfaction from teaching than from research. And there is a strong current of opinion in the university administration that says that research is a prize for the good boys who have written their courses. In some faculties there is even a feeling that science in general and scientific research in particular are expensive luxuries. But in spite of the difficulties the university has never been devoid of research.

Steven Rose and Ian Gass, professors respectively of Biology and Earth Sciences, managed to bring a nucleus of staff with them when they moved to Milton Keynes and have been gradually stepping up their activity ever since. The Department of Earth Sciences now produces more papers than any other British Earth Sciences Department except the Cambridge Department of Geophysics. The small staff (10 lecturers in the Biology Department) means that it is not feasible for everybody to work independently: intellectual companionship is only gained by joining a more or less interdisciplinary group. The obvious example is Rose's Brain Research Group, which involves five lectures and 15 others and is by far the largest research effort in the Biology Department. Another group, the Energy Group, was formed spontaneously during the preparation of a course on materials. Now the scientists, engineers, architects and economists in the group are studying

problems as various as the British gas industry and the development of a house heating system based on the same principles as the refrigerator cooling system.

Funding a problem

One of the programme's great advantages, of course, is cheapness. Funding is obviously a problem for an institution trying to grow at a time of economic crisis and government lack of sympathy with the universities. For an established group funding from the university and from outside sources is adequate if not princely. But for others there are difficulties: the university's approach is to fund a project initially but to expect it to attract outside funds to continue if it is any good; if the strings of published papers required by the SRC have not been written, the project is likely to founder.

Working conditions are not very comfortable and one of the problems in creating a stimulating academic environment is that people tend to spend a lot of their time at home writing course units. The permanent science building originally scheduled for 1974 will be ready in 1977 at the earliest and even this will not hold all staff: the biophysics and other groups temporarily housed in Oxford will stay there for at least another five years. That is not an unmitigated disaster—among the charms that Oxford possesses and Milton Keynes lacks are first-rate libraries and the ease with which temporary self-funded American

researchers may be attracted.

The Open University has always had research students—both internal students at Milton Keynes and Oxford and external students for whom the university finds an external supervisor near home. Many external students are technicians or hospital scientists and must of course have access to the equipment they need. Trying to do a PhD and a job at the same time sometimes causes insuperable problems: in many areas knowledge is increasing almost too fast for a part-time researcher to keep up, let alone make his own contribution.

At present higher degree students with Open University first degrees are rare, simply because so few Open University graduates have yet been produced. When they do start demanding higher degrees in large numbers there will be difficulties. The open university student, though probably more resourceful than the average British undergraduate, is not used to reading much outside his course text or doing much practical work. In many ways the Open University degree is closer to the American than to the conventional British one. American PhD students usually spend a couple of years doing course work before beginning research but the Open University offers no postgraduate courses. The prospects are not good: the undergraduate courses are voracious and the Department of Education and Science has not responded warmly to the suggestion that it might earmark certain sums for postgraduate courses. In terms of mere numbers this is understandable—at present there are 50,000 undergraduates and 400 graduate students—but the development of postgraduate courses will be valuable. □

Profits in academia

One way the Open University is hoping to cushion itself from the uncertainties of government funding is by setting up a company to market its educational materials. Marketing as a part of the university administration is as old as the university itself but it is hoped that Open University Educational Enterprises Ltd will greatly expand the business.

All is still in the air, though, while the university discusses the project with the Department of Education and Science which, after the resounding failure of a similar venture, British Museum Publications Ltd, is somewhat nervous of letting public funds be used as risk capital. The OU, however, is confident that the go-ahead will come in time for the company to start business on January 1 as planned. Large amounts of capital are not required as some of the present marketing division's profits are ploughed back into marketing. According to the university the talks are mainly to thrash out the right relationship of the new company to the university and to make sure that it is properly structured.

From the university's point of view, a company owned by the university has several advantages over a division of the university administration, among them the freedom the company would have to offer salesmen a suitably attractive salary instead of having to pay them on academic administration scales. The company may also clarify the copyright position—at present although the written word is the main teaching medium in the Open University the academics hold the copyright on their works as in any other university.

More than half the income from the sale of the Open University's books, tapes, films and cheap scientific equipment comes from abroad. The university feels there is plenty of room for the marketing company to expand: the marketing division cannot deal as well as it would like even with its present markets. If the new company succeeds, as is hoped, in increasing turnover from the present £700,000 a year to £1 million by 1980, it will be contributing a significant supplement to the £12 million government grant.

USA

Seeking Senate surgery

A radical overhaul of the Senate Committee system is being discussed in Washington. Colin Norman reports on the implications for scientific affairs

AN entertaining display of political horsetrading, perhaps culminating in a good public scrap, is about to unfold on Capitol Hill. For the first time in more than a quarter of a century members of the US Senate are being forced, somewhat reluctantly, to take a close look at that august body's confused and inefficient but immensely important system of legislative committees. Some sweeping reforms, which could wipe out entire committees and with them the power bases of a number of influential Senators, are under discussion.

The proposed reforms were put forward a few weeks ago by a special select committee. But because public attention was diverted by the marginally more interesting spectacle of the Presidential election and a third of the Senate were preoccupied with getting themselves elected, few people took much notice. The Senate is expected to take up the proposals soon after it reconvenes in January, however, and so they are now becoming a topic of intense interest on Capitol Hill.

There are a good many political obstacles to be overcome before the proposed reforms are accepted, but if they are ever implemented they will have a substantial effect on the way the Senate handles legislation on scientific and technological matters. For a start, responsibility for energy research and development would be placed in a single committee, the jurisdiction of the present Commerce Committee would be expanded to take in most non-military science and technology programmes, and the Joint Committee on Atomic Energy, which has charted the course of the United States' nuclear policy for some 30 years, would be abolished.

Overall, the proposals would reduce the numbers of Senate committees from 31 to 15, doing away with a variety of select, standing and joint committees, and realigning the jurisdictions of most of the remainder. The Senate's present 174 subcommittees would be cut down to about 100, and no Senator would be able to sit on more than 8 subcommittees. In short, the proposed reforms represent some pretty radical surgery, and they would bring about the first real changes in the Senate committee system for 30 years.

Even a cursory look at the system confirms the need for a knife. The Senate's committees are so sprawling

and their jurisdictions so confused that it is frequently difficult to tell which committee has authority over individual bills. Take energy research and development, for example. The Joint Committee is deep into one aspect of energy, so is the Interior Committee, the Public Works Committee, the Aeronautical and Space Science Committee, the Commerce Committee and the Labor and Public Welfare Committee. A couple of years ago, when a relatively non-controversial solar energy bill was passed by the House, no fewer than four Senate Committees claimed jurisdiction and it had to be approved by all of them before finally reaching the Senate floor.

But, though the need for reform is obvious, it is going to be a tough battle to get anything done. The problem is that Congressional committees, and to a lesser extent subcommittees, represent overlapping fiefdoms headed by powerful, and frequently elderly, chairmen whose authority has taken years to acquire. The chairmanship usually goes to the longest-serving member of the majority party on each committee, and with it comes a good deal of power to appoint committee staff, and to shape or even obstruct the passage of legislation. Thus any attempt at reform must first overcome the fact that a lot of powerful people are going to resist having their authority altered or even removed.

The House went through a mild reorganisation a couple of years ago in a move which gave the House Committee on Science and Technology a good deal more power. But those changes were only made after a couple of years' of intense negotiations and six days of shrill public debate. The Senate reforms may be equally difficult—moves are already afoot to try to shunt them aside by simply referring the whole matter to the Senate Rules Committee for further, prolonged study—but their proponents point out that conditions for change are more favourable now than at any time in the past several years. For one thing, there will be seventeen new faces in the Senate next January—a much higher turnover than usual. And for another, the chairmen of four committees threatened with the axe were either defeated or retired.

The following are the major changes proposed by the select committee in committees concerned with science and technology. It should be noted that the proposals would leave essentially untouched the real powerhouses, such as the Appropriations Committee, the

Armed Services Committee, the Finance Committee and the Judiciary Committee. Thus, some of the most powerful Senators won't be too badly affected, and appropriations for government agencies will continue to be handled by the same appropriations committees and subcommittees.

- It has been proposed that responsibility for non-military research and development policy should now fall under the present Commerce Committee, whose authority would be greatly expanded and whose name would be changed to the Committee on Commerce, Science and Transportation. The new committee would be responsible for keeping its eye on the activities of agencies such as the National Science Foundation, the Office of Science and Technology Policy, the National Aeronautics and Space Administration and the various agencies of the Departments of Commerce and Transportation. It would be the chief committee for federal research activities other than military, biomedical and energy programmes. If the proposed changes are accepted, they would cause the demise of the Aeronautical and Space Science Committee whose chairman, Frank Moss, was defeated at the polls in Utah.

- The change would also mean that Senator Kennedy would lose the authority he now holds over the National Science Foundation through his chairmanship of the NSF subcommittee of the Committee on Labor and Public Welfare. That committee would be expanded under the proposed reforms to become a Committee on Human Resources, and Kennedy is said to be negotiating to have NSF affairs consigned to it. It wouldn't be the most logical place for NSF, but at least Kennedy would be able to retain his jurisdiction.

The proposed Human Resources Committee would be responsible for, among other things, health and biomedical research, which means that Kennedy would retain much of his authority over the programmes of the National Institutes of Health.

- As for energy research and development, the select committee has proposed that the responsibilities of the present Interior Committee, headed by Senator Henry Jackson, should be expanded to include most federal energy development efforts. Renamed the Committee on Energy and Natural Resources, the new body would pick up responsibilities from the Joint Committee on Atomic Energy and a number of other committees. The proposal would put the knife into the back of the Joint Committee, the once-powerful unit which has shaped nuclear policy

since the second World War.

The Joint Committee is in trouble for other reasons, too. Next month, when Democratic members of the House meet to discuss the political agenda there, two nuclear critics, Clarence Long of Maryland and Jonathan Bingham of New York, will propose that the committee be scrapped and that some of its functions be transferred to the House Science and Technology Committee, among others. Thus, the Joint Committee is under combined attack in both the House and the Senate, and its chances of surviving are generally considered to be less than even. One point going against the committee is that five of its nine members, including the chairman, Senator John Pastore of Rhode Island, either retire at the end of this year or were defeated at the polls. Moreover, two of the most powerful members of the Joint Committee, Senator Jackson and Representative Mike McCormack, would stand to inherit some of its

authority in their own committees, so they probably wouldn't be too sorry to see the Joint Committee disappear. It should be noted that the Joint Committee has been consistently pro-nuclear, and its demise would be welcomed by anti-nuclear critics.

● Another major Senate change proposed by the select committee is the creation of a new committee on Environment and Public Works, founded mostly on the present Public Works Committee headed by Senator Jennings Randolph. It would be responsible for environmental programmes together with nuclear regulation, which would mean that responsibilities for developing and regulating nuclear power would be divided between separate committees.

The proposed reforms are expected to be one of the first items of business when the Senate reconvenes early in January, but negotiations are already under way behind the scenes, as Senators who stand to lose some of

their jurisdiction are striving to hang on to their authority.

It is quite possible that the opposition will be too strong and that the proposals will be quietly killed off or severely watered down by consigning them to the Rules Committee for further study. But at least the proponents of the reforms are preparing to put up a spirited fight. Senator Adlai Stevenson, the chairman of the select committee, is said to be threatening to introduce a resolution blocking the appointment of new senators to committees and the appointment of new committee chairmen if his proposals are simply shunted aside. Such a resolution could tie up the business of the Senate for a long time if it were approved. A more likely development is that differences will be settled by behind-the-scenes negotiations in the next few weeks, and a compromise reform plan will be worked out in conjunction with the Rules Committee. □

Genetic manipulation: enter the environmentalists

LAWYERS for two environmental organisations have filed a formal petition with the Department of Health, Education and Welfare (HEW) requesting extensive public hearings and the development of legally binding regulations to control all recombinant DNA experiments in the United States. It is the first time that environmentalist groups have formally entered the swirling dispute over the risks and benefits associated with recombinant DNA, and the petition is probably only the opening shot in what could develop into a lengthy legal fight.

Filed by the Environmental Defense Fund and the Natural Resources Defense Council, the petition has been endorsed by Robert L. Sinsheimer, chairman of the Division of Biology at California Institute of Technology. Sinsheimer, a leading critic of recently-issued safety guidelines governing recombinant DNA research supported by the National Institutes of Health (NIH), sent a letter to HEW along with the petition.

The petition requests two actions by HEW. First, public hearings should be held to allow interested parties to state their case and to have their views taken into account; and then HEW should develop binding regulations to control all recombinant DNA experiments in the United States. In the meantime, the petition asks HEW to extend the voluntary NIH guidelines to cover experiments supported by other agencies and by

non-government bodies.

The petition is clearly motivated by the belief that the NIH guidelines are inadequate to control the potential hazards associated with recombinant DNA research. It states that the guidelines "are the product of the deliberations of scientists who are now conducting recombinant DNA research", and argues that "little discussion was devoted to whether or not these experiments ought to be performed *at all*, even though the question was raised both by concerned laymen and by prominent scientists".

The petition also points out that the chief drawback in the guidelines is that they formally apply only to research supported by NIH, leaving industrial research essentially unregulated. Moreover, there is no requirement for federal monitoring to ensure that the guidelines are being followed. Those drawbacks are also bothering some state and local officials, in New York State for example.

The petition will probably be turned down on the grounds that HEW lacks authority to tell other agencies or private industry what to do, but the environmental groups are likely to press their case either in the courts or on Capitol Hill. Senator Edward Kennedy has already said that he may consider introducing legislation to make the NIH guidelines binding on everybody who wants to conduct recombinant DNA studies.

Meanwhile, an inter-agency task

force has been established in Washington to discuss ways in which the NIH guidelines can be extended to other federal agencies. According to one official concerned with the task force, it will also discuss the possibility of establishing a monitoring procedure to ensure that the guidelines are followed, and it will also look into what industry is doing and whether the federal government could (or should) regulate industrial recombinant DNA experiments. One possible outcome of the task force's deliberations is that the NIH guidelines may be made into legally binding regulations covering all agencies and industry as well. If so, that would accomplish some of the petition's demands.

The task force is headed by Dr Fredrickson, and consists of representatives of other federal agencies. It meets in private since it does not fall under the terms of the advisory committee act, and it is expected to come up with some recommendations by mid-January.

If it does recommend the adoption of legally binding regulations and a monitoring procedure, a key question would be which agency should take responsibility for enforcing them. NIH officials are anxious not to be placed in the position of both supporting and regulating the research, and the task may therefore fall to a regulatory agency such as the Occupational Safety and Health Administration.

USSR

Space programme: accentuating the cooperative

The Soviet Union will celebrate the twentieth anniversary of Sputnik-1 next year at the same time as the diamond jubilee of the October Revolution. Vera Rich reports

THE launching of Sputnik-1 on October 4, 1957, inaugurated a whole series of Soviet "firsts" in space, frequently co-ordinated (so far as the state of the art permitted) with some notable anniversary. The centenary of Lenin's birth was marked in 1971, for example, by the launch of the first orbiting space-station, Salyut 1; and it is entirely possible that the Soviet space programme is planning some equally prestigious "spectacular" for the sixtieth anniversary of the Revolution. The current emphasis, however, suggests that the year will be marked first and foremost by an extension of "fraternal cooperation" in space between the Soviet Union and her Comecon partners.

This trend is not a cover-up for the recent set-back to the Soviet space programme provided by the aborted Soyuz 23 mission when it failed to link up with the Salyut 5 station. On the contrary, it is perhaps best exemplified by the joint communique issued by Soviet Academician Boris Petrov and GDR Academician Karl Gröte, after the previous highly successful Soyuz flight. Soyuz 22 had carried a "multi-spectrum" camera from the Karl Zeiss (Jena) works, and was heralded as a new phase in Comecon cooperation in space. The same theme was enthusiastically repeated by the Soviet and Comecon media.

The presence of foreign equipment aboard a Soviet spacecraft is not new; French instruments were carried on Lunokhod 2 and by the Mars 5, 6, and 7 probes. Comecon has had its own space programme, Interkosmos, since 1967, and has launched 16 orbital satellites and 4 high altitude rockets. The Soviet Union supplies the rocketry for all Interkosmos launches, while her Comecon partners supply certain instruments, so the use of such instruments in a formally Soviet mission might seem a fairly predictable development. Why, then, was it greeted with such acclaim?

Propaganda plays a certain part: the current Comecon five-year plan, while temporarily soft-pedalling the final goal of total economic integration, is concentrating on a short term drive

(15-20 years) towards integration in certain significant areas, notably sophisticated instrumentation. The Petrov-Gröte communication clearly refers to this policy, stating that East German participation in Soyuz 22 was "part of the process of Socialist integration in one of the newest regions of contemporary science and technology".

The concept of an integrated science policy is, however, meeting with opposition from certain research bodies and institutions in the member countries of Comecon, particularly where, as in Poland, there is a long native scientific tradition. Such bodies have been openly accused of "autarchic" (that is, nationalist) tendencies, necessitating the intervention of Party and

Government. Emphasis on cooperation in such a prestigious field as space research might well be interpreted as simply a tactical measure to offset in the mind of the public the effect of this academic discontent.

Earlier this year it was announced that Interkosmos would start a manned space programme with multinational crews. The first launches are scheduled for 1977 and the cosmonauts are already in training. It would seem, however, that each crew is to include at least one Soviet cosmonaut. Since the Soyuz 11 tragedy, though, the Soyuz missions have used a two-man crew, instead of the previous three—a change apparently associated with the decision that the crew should wear space-suits during re-entry as a safety measure. If the current pattern continues, it will take at least eight flights for each country to get one representative in space.

Expeditions: resources rationally used?

The rational use of natural resources in the Soviet economy is a major target of the current five-year plan. It is also a dogma which can be invoked to justify most things. That includes geological and geographical expeditions, where the data obtained can be interpreted to relate to the needs of prospecting, oceanography, climatology and other fields of practical significance. In the case of the expeditions of summer 1976, the range is from the immediately practical to the extremely remote in terms of the economy's needs.

On the one hand, there was massive Soviet participation in the 200-strong joint Comecon expedition to Mongolia, which worked within a surveying programme aimed at ensuring 10-20 years' supply of fuel and material resources for the Comecon bloc. During this first field season some 7,000 km² was systematically surveyed, and several outcrops of "valuable raw materials" (so far unspecified) were located. The expedition is a long-term project; to facilitate its work in future seasons a special base is to be established next year on the outskirts of Ulan-Bator, the Mongolian capital, with administrative and living accommodation as well as such services as shops and a kindergarten.

Although even the most cautious planners could hardly doubt the practical value of the Mongolian expedi-

tion, they might feel a little different about the other major long-term project inaugurated this summer. This is the scheme to sink a 16-km borehole at Saatly in the Murganskaya steppe. This area is a "geological anomaly", where the crust is significantly thinner. In 1970, a pilot borehole was sunk to a depth of 6,240 m. If successful the new project will allow material to be recovered from the upper mantle. The theoretical value of such specimens would be immense; the most practical outcome of the expedition may well be the experience which the Soviet oil industry will gain in sophisticated drilling techniques.

One of the most practically-orientated expeditions this summer was that of the Siberian Energy Institute of the Soviet Academy of Sciences, which set out to survey possible power resources in the construction area of the new Baikal-Amur Mainline railway. The Baikal area has long been famous for its geographical and ecological riddles; this expedition discovered another, a complex of "classical mountain glaciers" at a relatively low altitude and unexpectedly far south. The plans for the railway have from the beginning incorporated a number of conservation measures aimed at preserving the unique Baikal habitat. The presence of these glaciers "in direct proximity of the line" is causing the relevant experts considerable concern.

The head of the cosmonaut training programme, Lieutenant General Vladimir Shatalov, has spoken in terms of a three-man crew, consisting of a Soviet commander and a flight engineer and research engineer from other Comecon countries. This suggests either a return to re-entry in shirt-sleeves or else the use of a larger spacecraft, and Shatalov has indicated that "in time" larger orbiting stations will be used, making it possible for the crews to include specialists from different fields. But he did not make it clear whether such stations would be in use by 1983, and present plans for Comecon participation go no further than this date.

It remains to be seen whether such joint missions form an integral feature of long term Soviet space planning, or whether, as in the case of the flight of the first (and only) woman cosmonaut Valentina Tereshkova, a policy hailed as a triumph of socialism may later be quietly phased out. The manned programme, however, is by no means the only new development of Interkosmos, nor in the long term is it the most significant.

Petrov and Gröte speak rather

vaguely of Comecon participation in "still more complex and interesting experiments". This may mean no more than the provision of equipment for Soviet spacecraft, a development that is virtually implicit in the "integration" policy which aims at increasing specialisation of the member countries. But Comecon is also to provide some of the ground facilities. Already the Comecon countries track the Soviet spacecraft. The accession of Cuba to Comecon provided an important new link in the network; new plans include the provision of various research facilities. A new astronomical observatory was recently opened in Prague as part of the Interkosmos programme.

Poland's contribution will be considerable—a Space Studies Centre within the Polish Academy of Sciences to include institutes of space physics and geodesy, earth and environmental resources, the application of space technologies, materials testing, and also a computer centre. According to Professor Stefan Piotrowski, a member of the Polish Academy of Sciences and also of the Interkosmos Council, the centre will work on methods of research into the effect of solar

activity on the ionosphere and atmosphere which, he says, will benefit communications, meteorology, agriculture and possibly medicine. The council will also draw up a programme of experiments to be carried out by manned spacecraft and satellites.

Although such facilities are designated part of the Interkosmos programme, it seems inevitable that the Soviet Union's own national space programme will also benefit from access to them; indeed, this would provide a further opportunity for "fraternal cooperation". However, certain joint Comecon projects have already evoked the criticism that the Soviet Union has made little contribution other than a site or the expertise, while the financial burden has fallen on her partners. However great the official acclaim of such cooperation, the possibility remains that those scientists already disenchanted with Comecon countries may view the new developments in the space programme not so much as a triumph for fraternal integration as a way for the Soviet Union to get routine research and development done at someone else's expense. □

NETHERLANDS

An unfavourable climate

Casper Schuurin reports on recent developments in science policy in Holland

THE Dutch Government is going to spend 2,560 million guilders (about £640 million) for research in 1977. Universities will use less than half (1,130 million), after a budget this year of 2,300 million. Industry plans to have 2,810 million guilders available next year for research and development after 2,510 million this year; at the end of last year industry had expected to spend 2,190 million in 1976, indicating that the climate for investment in research is not as favourable as it seemed. Some 390 guilders will be spent on research and development per head of the population.

These figures are part of the new budget presented to parliament by the science policy minister, Fokele Trip. He says science policy cannot be seen apart from the socio-economic development of the country: out of science policy a contribution should come to the selective growth of the economy which the government has outlined in the government memorandum on industrial policy issued earlier this year. Environmental factors, town and country plan-

ning and a policy to avoid the wasteful use of energy and resources all form part of that selective growth policy.

On the energy front 60 million guilders will be available for research as the specially formed fund for the sodium-cooled fast breeder reactor in Kalkar will be abolished. This will be used mainly for programmes other than in the nuclear field. It is surprising, however, that in the plans for research up to 1981 which were presented along with the science budget, the nuclear energy component will increase while the total energy research and development budget will hardly be more in 1981 than in 1977. The future for alternative energy sources is therefore looking very bright at the moment.

Mr Trip is also planning to spend more money for a popularisation of science. For five years the University of Amsterdam has organised courses for scientists to write articles for a larger audience beyond their own discipline, and it will now receive a government subsidy. Other universities are also starting such a course. At the School for Journalism a training-course for science writing will also be introduced with ministerial money, and the Royal Dutch Academy of Sciences is conducting a study on a science information unit to improve "science-

Trip: not available

society" communications; Dutch universities and some research institutes are, however, already more or less active in this respect.

The science budget received a favourable reception in the parliament's special commission on science policy. Mr Trip has said that for personal reasons he is not available for a government post after the elections in May 1977, and feels that a new minister for science policy is necessary. He says he will leave behind a sort of "last will" describing how best the position of such a minister can be used. □

IN BRIEF

Nuclear trade

Export of Australian uranium ore to the United States, Japan and West Germany, embargoed for four years, is to be increased but not matched by an extension of mining operations. Export permits are to be issued for Rio Tinto-Zinc to meet existing contracts, but exploitation of other mines must await the further findings of the Fox environmental enquiry.

Canadian sternness over the proposed French sale of a nuclear reprocessing plant to Pakistan has meanwhile resulted in France letting it be known that if Pakistan chose to cancel the contract no strong objections would be raised. The French have no intention of backing out themselves, in spite of modifications in their nuclear export policy acknowledging the dangers of nuclear proliferation. Canada provided Pakistan's only nuclear reactor, and has threatened to supply fuel for only

two years instead of six if Pakistan acquires a reprocessing plant.

● The informal association of nuclear exporters which met in London last week has grown to 15 with the addition of Switzerland, with observer status only. Members of the group have now been named officially. They are the United States, the Soviet Union, France, Britain, West Germany, Japan, Canada, Belgium, Sweden, The Netherlands, Italy, Switzerland, East Germany, Poland and Czechoslovakia.

Genetic proposals: reactions

The Institute of Biology has now expressed its concern about the UK Health and Safety Commission's proposals for regulating genetic manipulation experiments in Britain. Commenting last week on the Commission's consultative document, which was circulated at the same time as the Williams Committee report, the Insti-

tute says it is "neither practicable nor desirable" to have both a blanket regulation requiring advance notice to be given on all experiments and a clause exempting "what is likely to be over 90% of microbiological experiments".

The Commission, the Institute says, "has not available, nor will it be able to recruit, sufficient suitably qualified staff to deal with notifications and exemptions", and goes on to suggest that its involvement should be "solely as a body able to enforce recommendations" of GMAG, the advisory group recommended by Williams and now being established by the DES.

The Association of University Teachers (AUT) also made its views known last week. Making similar criticisms to those of the Institute of Biology, the AUT asks that the Commission think again "on the lines that it puts forward a much stricter definition of the experiments covered".

Our farm animals, as they exist today, have been produced by selective breeding from wild ancestors. Domestic cattle in Europe and North America grow rapidly when kept warm and dry with an ample supply of nutritious feed, and they give milk in large volumes under similar, unnatural conditions. Unless grazed on lush pastures of cultivated grasses whose productivity is maintained by the plentiful use of fertilisers, or unless they receive concentrated high-protein rations, their yield of meat and milk falls well below their potential. So long as the world produces a surplus of food to support this type of husbandry, the breeds which are at present the most numerous—the Friesian and the Charolais for instance—will retain their popularity.

As new and more productive types of cattle have been produced, so many of the older breeds have become less common, and some are already extinct. Similar processes have operated with sheep, pigs and poultry. The variety of the livestock on our farms is rapidly being reduced.

Most farmers have welcomed the simplification of having only a few well-characterised breeds of animals to choose from, and have not been worried by the disappearance of so many others. However, there has recently been more concern about the loss of so many breeds which have evolved during the last two thousand years, particularly as the original ancestors of the breeds cannot now be identified. Organisations such as the Rare Breeds Survival Trust have been established, and the results of

their efforts can be seen at the Cotswold Farm Park in England, and in Folk Museums in Scandinavia.

Many who wish to save our old breeds probably do so for senti-

Past breeder**KENNETH MELLANBY**

mental reasons, but they also justify their policy by suggesting that it has an educational value, to teach children and students about the history of farming. It is also claimed that some of the old breeds may be able to contribute valuable genes to future breeding programmes, and thus produce animals with virtues missing from existing commercial strains. Plant breeders have used ancestral forms of potatoes and cereals in this way, and animals might be treated in a similar manner. Unfortunately, though this may still be a possibility, most

breeders of cattle and sheep think that there is little valuable genetic material in the small surviving stocks of most old breeds. This opinion may be coloured by their preoccupation with animals suitable for intensive farming, where hardiness and the ability to survive are no longer sought.

I believe that we should look again at some old breeds as meat producers in their own right. As the world population grows, there will be less surplus food for intensive animal rearing. Our best land, in all countries, will be increasingly needed for crops for human consumption, and marginal land in the uplands will become more important for raising livestock. Already it has been shown that non-domestic species such as the Red Deer in Scotland and the Eland in Africa may produce meat more efficiently than cattle or sheep on poor grazing, and some scientists think we should make more effort to find new species to domesticate. Unfortunately deer and antelope have proved difficult to manage in large numbers, so their potential is limited.

Some of the old breeds may be as good at making meat from poor herbage, and we may benefit from their heritage of domestication. I have kept Soay sheep, the breed still found on the islands of St Kilda off the west coast of Scotland and apparently little changed since they were herded by Neolithic man, on pasture on which ordinary domestic breeds would have starved. The animals flourished and bred. Other breeds of sheep and cattle, unsuitable for the intensive farm, might do equally well.

correspondence

The toxicity of plutonium

SIR,—In your editorial "Take your time Mr Benn" published on September 30 you discuss the Report of the Royal Commission on Environmental Pollution. You state that "the report first reviews what is known in radiobiology with particular attention to plutonium", and that "independent consultants were brought in. . . . The consultants' reports have not been published." Two of the signatories of this letter (F.W.S. and J.V.) are acknowledged by name in paragraph 537 of the report. We wish to make it clear that the two other signatories (R.D. and P.L.), who are members of the Commission, take full responsibility for Chapter II on Radioactivity and Radiobiology in the report. This was not seen by the consultants at any time prior to publication. In fact they disagree with several of the statements made in this chapter.

In paragraph 66, for instance, the statement that "plutonium isotopes are retained in the body once they gain admittance" is certainly misleading. Excretion does occur though it is not rapid, while no mention is made in paragraph 55 of the salient fact that the energy deposited in the tissues by the strontium 90 decay process is about 200 times greater than that deposited by tritium.

Further, the greater part of the evidence given to the Commission by the consultants has already been published in their joint paper in *Nature* (February 19, 1976) entitled "Hazards of plutonium with special reference to the skeleton", and in a paper by Janet Vaughan entitled "Plutonium—a possible leukaemic risk", in W. S. S. Jee (Ed.), *Health Effects of Plutonium and Radium*, 691–705, (J. W. Press, Salt Lake City, Utah; 1976). In fact references to these two papers were made by the Commission in Chapter II and in their bibliography.

In their written evidence to the Commission the consultants stated "We are in agreement with the conclusions arrived at by the Medical Research Council¹ and the National Radiological Protection Board² on the risk to the lung and on the question of the hot particle." Reference to both these matters was made in their paper published in February in *Nature*, and in a paper published by Mayneord and Clarke³ on which their discussion was

partly based and which was also published in the same issue of *Nature* under the title "Quantitative assessment of carcinogenic risks associated with hot particles". The substance of the consultants' comments on papers submitted by the National Radiological Protection Board on the numbers of deaths from leukaemia at the Windscale reprocessing plant are contained in paragraphs 74 and 75 of the Report.

Genetic manipulation

SIR,—The contribution of John Locke, the Director of the Health and Safety Executive, to the debate on genetic manipulation raises a new and disturbing issue. The Director claims that "the techniques described as 'genetic engineering' should be permitted where they offer prospects of social benefit" subject to safety precautions. So we learn that the safety of experiments is not the only criterion on which they are to be judged; officials are also to pass judgment on the social benefit of genetic experiments.

The ethical problems were not even discussed in the Williams Report, which confined itself solely to safety considerations in genetic manipulation. Clearly the Health and Safety people have no mandate to assess the social benefits of work. Besides the safety aspects of work in genetics, ethical problems could arise and these need very full debate before they have any in-

fluence on executive action.

Human anatomy

SIR,—The interest in descriptive asymmetry shown in *Nature's* pages indicates that the classic German treatise on the subject¹, reprinted in 1970, deserves recognition by the English-speaking world. Asymmetry of human limbs, and much else, has a large literature but lacks a recent review. There is even a more recent paper² devoted to a positive correlation between handedness and scrotal asymmetry. There are also by now several dozen analytical treatments^{3–8}; fluctuating asymmetry (but not other kinds) is a measure of the imprecision of development.

Careers in science

SIR,—There has been a great deal of discussion recently about possible short term cutbacks in 'big science' projects. Nowhere have the effects on the careers of scores of research students been discussed. Simultaneously there are complaints about the lack of prospective students for university science courses. Is it not possible that these two sets of circumstances are directly related?

(Name and address supplied)

To be or not to be

SIR,—Isn't isn't is'nt! (October 7, page i).

Yours faithfully,

KENNETH E. APT

news and views

Coexistence with insect pests

from Robert M. May

INSECTS have shared man's crops, and transmitted his diseases, from the earliest times. On a tomb erected towards the end of the Old Kingdom in Ancient Egypt (about 2,300 BC) locusts are shown eating cereals, and the Book of Joel (1, verse 4) records a remarkable sequence of entomological misfortunes wherein "that which the palmerworm hath left hath the locust eaten; and that which the locust hath left hath the cankerworm eaten; and that which the cankerworm hath left hath the caterpillar eaten". Today at least one person in six is suffering from some form of insect-borne disease (primarily 300 million from filariasis and 200 million from malaria: see *Nature*, **262**, 85; 1976), and world crop losses are estimated around 10–15%.

Agricultural societies have evolved a variety of empirical practices aimed at reducing the depredations of crop pests. In the absence of detailed understanding of the pest's population dynamics, it is hard to be sure whether any one such practice represents the optimal control strategy, or the best among similar strategies (but inferior to some qualitatively different strategy), or simply ignorance hardened into habit. Chiang (*Science*, **192**, 675; 1976) has reviewed a most interesting series of Chinese texts, which *inter alia* codify this sort of folk wisdom: it is advised, for example, that the top leaves and buds of cotton plants should be examined at 3-day intervals for eggs of the cotton bollworm, and chemical control initiated above a threshold of 15 eggs for 100 plants.

An analytical approach to the control of crop pests and forest defoliators has been pioneered by Watt, Holling, Huffaker and others. Here one starts with a fairly detailed model for the population dynamics, and tries to determine the relevant parameters from field and laboratory experiments: in effect one tries to decide whether 5 or 15 or 50 is the appropriate number of bollworm eggs, or whether some qualitatively different strategy may be better. A notable example of this approach centres on the froghopper, *Aeneolamia varia saccharina*, which

attacks sugar cane in Trinidad and elsewhere (Conway *et al.*, in *Study of Agricultural Systems*, edit. by G. E. Dalton; Applied Science, London, 1975; and Conway, chapter 14 in *Theoretical Ecology: Principles and Applications*, edit. by May, R. M.; Blackwell, Oxford, 1976). Starting from a basic model for the dynamical behaviour of the population, the effects of various control strategies are determined. The economic costs and benefits of these strategies are then calculated, in Trinidadian dollars. The optimum strategy turns out to depend mainly on the size of the first-generation brood of hoppers, and thence on the weather. Optimal control can nevertheless be maintained by use of dynamic programming techniques.

On a more general level, Southwood (in his opening address to the 15th International Congress on Entomology, in Washington, DC on August 18) and Conway (*op. cit.*) have recently used contemporary ecological notions to bring some order and pattern to the bewildering variety of dynamical behaviour of insect pests.

At one end of a continuum are the 'r pests' (*Nature*, **257**, 737; 1975), which are characteristic of unpredictable, transient or patchy habitats: examples are desert locusts or fruit flies. Their strategy is one of boom and bust, and r pests will virtually always achieve pest level if enough of them invade the crops and there is adequate time before harvest. At the other extreme, 'K pests' occur in stable habitats. Their populations are typically steady and relatively low, and they do not have a serious impact on their natural food. K pests achieve pest status when their low level of harvesting is nonetheless unacceptable to man (as is codlin infestation in a fraction of the apple crop, or ectoparasite holes in a commercial hide), or when the introduction of plants or animals to new areas disturbs natural balances (the mirids that, even at low population levels, are destructive of the cocoa trees introduced into West Africa and the Far East inflict relatively little damage on their natural host plants;

trypanosomiasis, carried by tsetse flies, is rarely lethal to the indigenous African fauna, but is a problem for man and his domestic animals). In between these extremes are the majority of deciduous forest defoliators, fruit insects and some vegetable pests. These 'intermediate pests' are for much of the time held at a lower equilibrium point by natural enemies, but they occasionally escape this natural control and reach outbreak levels. Those near the r end of the spectrum, such as aphids, escape most frequently. Intermediate pests may become r pests when they are introduced to new areas where their natural enemies are absent: examples of such introductions, where the organisms are not significant nuisances in their countries of origin, are the gypsy moth, *Lymantria dispar*, to North America, and the giant African snail, *Achatina fulica*, to Pacific islands. This continuum of r, intermediate and K pests is elaborated and fleshed out with numerical examples in Southwood and Comins (*J. Anim. Ecol.*, **45**, 949; 1976).

Southwood observed in his opening address that "this knowledge of the underlying population dynamics of different pests gives useful indications of the appropriate pest control methods". The term control is here used in a precise and sensible way to mean reducing the pest impact to a level where the marginal cost of further measures would exceed the marginal revenue to be gained thereby.

In Southwood's words, "r pests are always fluctuating, and therefore any appeal to the stability of natural ecosystems is spurious and foredoomed to failure". Cultural control techniques will depend on reducing the chances of pest invasion. Paradoxically, and contrary to tenets laid down in simple ecology tracts, one way of doing this is to increase the scale of a monoculture, thus increasing the area-to-perimeter ratio and heightening the degree of isolation (Way, in *Biology in Pest and Disease Control*, edit. by Price-Jones and Solomon; Blackwell, Oxford, 1974). However, in these "inherently booming populations, in-

secticides will remain the most powerful technique: their rational use will demand the development of better methods of forecasting and assessing pest outbreaks".

Intermediate pests should be kept below their release point, so that the population is stabilised by natural enemies. Southwood emphasises that these are the pests against which biological control, or integrated control with a significant natural enemy component, must be the dominant strategy. When pests of this intermediate kind are present in an ecosystem, the mindless "prophylactic" application of insecticides is likely to eliminate the lower equilibrium point controlled by natural enemies, thus leading to outbreaks of "secondary" or "upset" pests.

K pests will be the most susceptible to eradication, or at least to being kept at low population levels. They often have complex reproductive tactics and these, together with the relatively low rate of recruitment of the adult stage, make them vulnerable to techniques such as the release of sterile males (as

in Knippling's work on the screw-worm fly, *Cochliomyia hominivorax*) or the use of pheromones.

These insights imply that insecticides are likely to remain a vital tool in engineering our coexistence with insects. On the other hand, the past 30 years have seen a faster-than-exponential rise in the proportion of pests resistant to insecticides: over 200 species of significant pests are now resistant to one or more chemical compounds. Eradication programmes based on the heavy, widespread and prolonged use of insecticides are not only biologically naive and usually futile, but they also squander a valuable resource—the life of the insecticide. The obvious conclusion, emphasised by Southwood and by the US National Academy of Sciences study committee on pest control (*Science*, **191**, 836; 1976), is that we must in the future be more selective in our use of insecticides, and more efficient in their application, than we have been in the past. In this endeavour, analytical understanding of the population dynamics is a crucial ingredient. □

Giordano Bruno, the Moon's latest large crater

from David W. Hughes

To the observer with a telescope the Moon's surface seems unchangeable and over three centuries of study has revealed no well documented alteration. This is hardly surprising considering that, in the absence of erosion, the cratered surface has taken more than four thousand million years to get to its present state. Also recent estimates of the present day cratering rate (Shoemaker, *NASA Tech. Rep.* No. 32-700) indicate that a 1-km crater (which is just on the seeing limit for Earth-based telescopes) will only be formed on average once every 4×10^7 yr. A crater of 20 km or larger is produced every 3×10^{11} yr, which in view of the fact that there are many such craters on the Moon is ample indication of how the large body influx and thus the cratering rate has decreased with time.

The above points make the paper by Jack Hartung (State University of New York, Stony Brook) in the recent edition of *Meteoritics* (**11**, 187; 1976) all the more fascinating. Hartung retells the report of five men who happened to be looking at the new Moon early in the evening of July 18, 1178. The Moon was then 1.5 d past new and would have been seen as a thin waxing crescent setting near the western horizon in the evening twilight glow.

"... suddenly the upper horn split in two. From the midpoint of this division a flaming torch sprang up, spewing out over a considerable distance fire, hot coals and sparks. Meanwhile the body of the Moon which was below writhed, as it were in anxiety ... and throbbed like a wounded snake. Afterwards it resumed its proper state. This phenomenon was repeated a dozen times or more, the flames assuming various twisting shapes at random and then returning to normal. Then after these transformations the Moon from horn to horn, that is along its whole length took on a blackish appearance".

This report was given on oath to Gervase of Canterbury and incorporated in his mediaeval chronicles (edit. by Stubbs, W., *The Historical Works of Gervase of Canterbury*, **1**, Her Majesty's Stationery Office, London, 1879).

It is highly unlikely that some Earth-based event caused this phenomenon although an unusual cloud layer or turbulence in our atmosphere or the entry of a meteoroid along the line of sight to the Moon could have been responsible. The report, however, repeatedly refers to the Moon and does not mention clouds or sky specifically.

Hartung suggests that the description

is consistent with the occurrence of a large impact on the lunar surface. "The upper horn split in two"—part of the sunlit crescent became obscured by the cloud of ejecta produced by the impact. "A flaming torch sprang up, spewing out fire, hot coals and sparks"—a vivid description of the hot dust, molten rocks and incandescent gases ejected from the impact point. "The moon writhed and throbbed like a wounded snake"—the Moon seen through the highly turbulent temporary atmosphere produced by the ejecta. "This phenomenon was repeated a dozen times or more"—the production of secondary impact craters by large pieces of ejecta that had insufficient energy to escape from the gravitational attraction of the Moon and fell back onto its surface. "The Moon then took on a blackish appearance"—the entire Moon's now having a temporary dusty atmosphere which blocked a significant amount of the light reflected from its surface.

Does such a newly formed crater exist on the Moon? The event occurred near the midpoint of the upper horn of the new Moon so the area around latitude 45° north, longitude 90° east is a good place to start looking. It was also easily visible to the naked eye indicating that the ejecta cloud was more than 100 km across. The crater should therefore be more than 10 km in size. Also a recent crater should have a bright ray system (rays being constant-width fingers of light coloured ejecta which radiate from the area of the central crater along the arcs of lunar great circles).

Searching the area between latitude 30° and 60° N and longitude 75° and 105° E using Lunar Orbiter and Apollo mission photographs Hartung soon found a likely candidate, the crater Giordano Bruno (latitude 30° N, longitude 103° E). This is 20 km in diameter and is surrounded by very prominent bright rays which extend for hundreds of km (see NASA photograph AS8-12-2209). In fact Giordano Bruno has the largest ray length-to-crater diameter ratio of all the lunar craters. The crater rim is also very sharp and has not yet been rounded off by the "gardening" process as have the older craters (Fig. 1).

It is interesting to think how this theory can be verified. Assuming that the observation was made near Canterbury, Hartung finds that on June 18, 1178, the Sun set at about 20.15, the Moon setting about 45 min later, so the event must have occurred between 20.15 and 21.00 GMT. Also making the assumption that the Sun had to have set for the event to be visible, limits the points on the Earth from which it could be seen to a band stretching from the region between

Fig. 1 A Lunar Orbiter photograph of the Moon's latest large crater, Giordano Bruno. The impact producing this crater was observed from near Canterbury, England at around 20.40 Greenwich Mean Time on June 18, AD 1178 (courtesy of NASA).

Oslo, Norway and Stockholm, Sweden, through southern England and the north-west corners of France and Spain, west of the Canary Islands and along the south-east coast of Brazil. Mediaeval records from these countries should be searched to see if the event is mentioned.

The crater itself might still have the signature of its recent formation. Microwave sensors on board a lunar polar orbiter may still be able to detect a higher temperature inside the crater, attributable to the heat generated during the original impact. Also rocks ejected from the crater will have been exposed to space for only 800 yr and will have a distinctive population of micrometeorite craters and cosmic ray particle tracks. The return of such samples to Earth will not only prove the craters to be of recent origin but will also be a valuable clue to other long time-scale Solar System processes such as the implantation rate of solar wind particles and cosmic ray nuclear reaction rates.

All in all this crater identification is most exciting. Even taking Baldwin's (*Icarus*, 14, 36; 1971) Earth cratering rate as applicable to the Moon the chances of anyone observing the formation of a large lunar crater on the Earth-facing side of the Moon during the millennia of recorded history (say 3,000 yr) is 1 in 2,000. Because observations have not been made continuously, may not have been recorded or the records might have been lost, the probability becomes extremely small and the Canterbury record even more fortuitous. Discounting the dubious and controversial changes claimed to have occurred to the crater Linné in Mare Serenitatis (Fauth, *Astr. Rundschau*, 3, 172; 1901) Giordano Bruno is unique, being the only large lunar

crater to be formed in recent history and as such it becomes a prime lunar target for future space exploration.

Drugs and body temperature

from a Correspondent

The Third Symposium of The Pharmacology of Thermoregulation, was held at Banff, Canada, on September 14-17, 1976.

"AND now for something completely different!" This sentiment imbued many of the presentations at the conference. 'Thermopharmacology', a term coined in 1969, is devoted to the relation between the action of a drug and an animal's body temperature in all its complexity, and it is difficult to know where pharmacology ends and physiology begins in this subdiscipline. In fact, much of this conference did deal with functional rather than pharmacological questions—particularly those centred on the body temperature control mechanism located in the brain. Overall, there were several exciting highlights.

"What is the purpose of a fever and what is its value to the survival of the organism?" In asking this question, M. Kluger (University of Michigan Medical School) laid a potential bombshell in the physician's lap. In an elegant experiment, he demonstrated that aspirin is not beneficial after all

when given to a rabbit, desert iguana or other animal during a fever caused by bacteria. In fact, if given a dose of aspirin that prevents fever from developing, a large proportion of the animals die. Following on, J. Covert and W. Reynolds (Pennsylvania State University) reported independently that goldfish, small-mouthed bass and other fish manifest a "behavioural fever". After infection with bacteria, the poikilotherm, living in an aquarium heated along a gradient, swims to warmer water. If kept in cooler water, the bacteria-laden fish dies. If an aspirin-like compound is dissolved in the aquarium water, an afflicted fish will likewise succumb, since it fails to swim to warmer water after the antipyretic drug is taken in, presumably through the gill network. Even though a fish does not regulate its body temperature in the same way as a mammal, the nervous system of this evolutionarily more primitive animal is nevertheless affected by the pathogen. So aspirin usage may have been dealt yet another blow.

A new "activator substance" released by white blood cells was described by G. Gander (Medical College of Virginia). This protein possesses the property of triggering other types of inflammatory cells to release a pyrogen. The "activator" could account for the fever seen in a patient who is stricken with a heart attack yet exhibits no signs of an infectious agent. Observations by E. Atkins (Yale University) implicate a lymphokine released from blood lymphocytes that causes other blood cells (monocytes) to produce pyrogen. A fascinating question now is whether the lymphokine and the "activator" are one and the same.

Along these lines, a new assay for

identifying "pyrogenicity" (the fever-producing capacity of a substance) was evaluated by G. Meers (Calgary Medical School). If *Limulus* (horseshoe crab) blood is mixed in solution with quite minute amounts of bacteria, the crab's blood thickens. Conceivably, in a patient who has contracted an infectious disease, bacterial counts in blood could be quantitated; alternatively, the crab blood assay could be used for the relatively rapid screening of drug solutions intended for administration to the human patient.

In several quarters, pockets of distinct but congenial controversy arose. What, for example, is the role of the metabolic substrate cyclic AMP in the temperature control mechanism? A. Milton (University of Aberdeen) reported that cyclic AMP and other cyclic nucleotides produce hypothermia on their injection into the hypothalamus of the cat. But exposure of the animal to a hot or cold environment fails to alter the central level of cyclic AMP. A contrary result was then presented by C. Rosendorff (University of Witwatersrand, Johannesburg) who contended that, in the rabbit, cyclic AMP evokes hyperthermia and indicated that cyclic AMP could be an intermediary for producing fever. An easy resolution would be to fall back upon "species difference" as an explanation. Recent evidence continues to accumulate which implies that different mammalian species have similar neural and humoral mechanisms for heat gain and heat loss. In fact, it was revealed that in the rabbit 5-hydroxytryptamine (5-HT) causes hyperthermia, and noradrenaline, hypothermia, which are precisely the same responses seen in the cat, rat, monkey and other species. Expertise in technique, or lack thereof, rather than nature's capriciousness may ultimately explain the so-called "species difference". In any event, the "second messenger" question concerning cyclic AMP has yet to be resolved.

An even more intriguing controversy is the role of the prostaglandins (PG) in the brain and the part they play in fever induced by bacteria. Ostensibly, bacteria cause an increased synthesis and/or release of a PG in the brain which subsequently produces a long-lasting hyperthermia. R. Hellon (National Institute for Medical Research, London) shook the theory by announcing that an antagonist of PGE₂ (a compound coded as SC 19-220) blocks a fever evoked by this prostaglandin. Thus, if the pyrogen-PGE theory were correct, this antagonist should likewise prevent bacterial fever. But it does not. This suggests an alternative mediator. R. Myers (Purdue University) troubled

the waters further by showing that a low dose of aspirin perfused in the cat's hypothalamus, although blocking PGE activity in this structure, fails to prevent a bacterial fever from developing. However, 5-HT activity in the hypothalamus increases simultaneously with the rise in body temperature after infection with bacteria. Thus, 5-HT may be the mysterious intermediary in the hypothalamus after all. C. Rosendorff (Johannesburg) informally countered that a part of the PGE hypothesis may still be valid, since a precursor of PGE or a factor such as an endoperoxide (thromboxane) in an alternative pathway could be causal intermediaries. Feldberg ended by describing how PG-induced and other fevers can now be examined in the anaesthetised animal, given the appropriate anaesthetic. The brain mechanism responsible for fever and its development is still tantalisingly elusive.

Ionic mechanisms in the hypothalamus also exert an apparent influence in the final common neuronal pathway underlying temperature control. D. Jones (Calgary Medical School) showed that the hypothermia induced by calcium ion perfusion of the cat's hypothalamus is antagonised by adding glucose to the perfusate. This observation suggests that a local energy substrate can modify the ionic activity of the posterior hypothalamus. The endogenous activity of Ca²⁺ ions, traced in the same region of the cat's brain by R. Myers (Purdue), changes in an opposite direction when the animal is warm or cold as well as when its hypothalamic thermoreceptors are warmed or cooled. In spite of this, the issue of whether or not an ionic mechanism does underlie the typical set-point temperature of 37 °C persists.

Ingenious techniques and their use were also emphasised. For example, the behavioural assessment of drugs that affect temperature regulation is now a popular procedure for deciding whether or not an animal will try to avoid being cold or warm after a drug is administered (E. Adair, Yale; E. Satinoff, University of Illinois). Although the importance of diurnal rhythms was also forcefully stressed by F. Halberg (University of Minnesota), one wonders whether the use of a control animal at the same time of day or night as an experimental subject would really make it possible to interpret let us say, a thermal effect of a given drug. Finally, the radioactive microsphere techniques developed recently were described by R. Hales (CSIRO, Sydney). These techniques are useful in obtaining a comprehensive picture of the effects of thermal stimulation on the regional distribution of cardiac

output and blood flow.

With the advent of the Feldberg-Myers monoamine theory of thermoregulation more than 10 years ago, pharmacologists have often concluded that a drug affecting body temperature does so by altering the balance between 5-HT and noradrenaline activity in the animal's hypothalamus—the essence of this theory. At the conference, it was evident that endogenous substances other than these amines will have to receive equal time at the research bench. Thyroid releasing hormone (TRH), prostaglandins, calcium, dopamine and other substances could be important factors mediating the brain's response to a drug given systemically. Of course, the relevance of these substances to synaptic events with regard to the hitherto prominent role of biogenic amines is still uncertain. □

Control systems in higher plants

from John A. Milburn

A symposium entitled Integration of Activity in the Higher Plant was held in Durham, under the auspices of the Society for Experimental Biology on September 4-9, 1976. The proceedings will be published.

BUMBLE-BEE flight physiology and rocket guidance systems are unexpected topics to meet in a plant physiology symposium. Nevertheless such examples served to illustrate the theme of the meeting, although those expecting papers on integration may have been disappointed; most emphasis was on control systems, probably because information on integration is so sparse.

The regulation of the heating up of the *Arum* spadix has been studied by T. ap Rees (University of Cambridge). Biochemically, the *Arum* spadix is a curiosity: in nature it heats up to more than 10 °C above ambient temperature, releasing a scent that attracts *Psychoda* midges which pollinate the flower. Heating is achieved by intense respiration comparable to that in the most physiologically active tissues such as the flight muscle of bats, birds and insects. This exaggerated respiratory system is used by ap Rees to study the inter-relation between glycolysis and the pentose phosphate pathways. A search for a mechanism in plants like the 'free-wheeling' or 'futile' cycles, responsible for warming up bumble-bee flight muscles in cold weather, has not been successful in *Arum*.

Why do stored seeds lose their viability? D. J. Osborne and colleagues (ARC Unit of Developmental Botany, Cambridge) attribute the loss of capacity of rye grains to germinate, to the progressive proliferation of embryonic lesions. With time, lesions in embryonic tissues increase beyond the point at which germination is possible, producing a state in which rye is 'deader than dead'. Lesion formation seems to result in failure to reactivate nucleic acid and protein synthesis sufficiently rapidly. Curiously, if rye grains are subjected to a preliminary brief wetting and drying cycle before sowing, reactivation is improved and viability and embryo vigour are enhanced over controls.

One would think that the flow of the transpiration stream through plant organs would have few mysteries by now since the water flow is generally believed to be regulated predominantly by the physical properties of the cell walls. On this basis the hydraulic conductance should be constant irrespective of the water potential gradient. J. S. Boyer's (University of Illinois, Urbana), results, like those from other laboratories, show that conductance increases dramatically as the water pressure gradient increases, which is not expected of a simple physical system. There was no obvious agreement as to the explanation of this intriguing phenomenon.

Generations of students have deduced cell turgor pressures by immersing pieces of tissue in osmotic solutions on the assumption that the internal solute concentration remains constant. This assumption is now strongly challenged by U. Zimmermann (Kernforschungsanlage, Jülich) who has measured the turgor pressure of single cells using a microprobe and pressure transducer. It is clear that cells respond directly to turgor pressure because, in addition to the anticipated water transport, the injection of inert fluid into cells produces immediate changes in the fluxes of solutes, especially potassium. Similar methods have been used to determine the elastic modulus of *Valonia* and *Mesembryanthemum* cells. How pressure modifies ion fluxes is a mystery. The geometry of the plasma membrane is apparently disturbed but the full explanation will be more complex. Although cell membranes can be compressed mechanically the technique is tedious but Zimmermann has introduced a revolutionary electrical method which charges membranes in the same way as the dielectric of a capacitor. Many new advances can be expected of this technique which has already been used to punch temporary holes in erythrocyte mem-

branes, causing them to absorb drugs. These erythrocytes can be reinjected and are being tested for greater control in the treatment of cancer.

The regulation of ions and solutes in cells and plant organs was outlined by J. A. Raven (University of Dundee), then M. G. Pitman and W. J. Cram (University of Sydney). Nowadays the driving system supplying energy for ion transport is widely believed to depend on proton pumping in accordance with Mitchell's chemiosmotic hypothesis. Proton pumping, if linked directly or indirectly to other ionic fluxes can explain many physiological responses, such as stomatal regulation, auxin transport and cell expansion, in addition to ion uptake by plant roots. The lipid bilayer of cell membranes has a high electrical and hydraulic resistance and to drive solutes at the rates commonly observed the membranes must contain ion pumps. The regulatory control of ion pumping is seen in the response to specific ions and also to growth regulating substances. In whole plants the uptake of cations and anions tends to be balanced and proportional to the amount of shoot growth but how the plant maintains the correct balance is not known. Is carboxylic acid production in leaves sufficient to balance cation uptake, for example, and is the extrusion of hydrogen ions from roots sufficient to explain cation uptake?

The orientation of plant organs requires sensing and response systems analogous to those in guided rockets, according to M. B. Wilkins (University of Glasgow) explaining recent progress in research on phototropic and geotropic responses. A strong plea was made for greater precision in describing and interpreting "hormone" experiments. Bioassays are too ambiguous for critical work and must be supplanted by physicochemical techniques such as mass spectrometry, used recently to confirm that the coleoptile geo and phototropic responses are in fact caused by indole acetic acid (IAA). Control systems are complex, varying between different organs and tissues and involving an interplay of growth promoters and inhibitors which operate in minute dosages. In *Zea* roots, growth inhibitors are undoubtedly involved in geotropic curvature, current evidence favouring a role for abscisic acid (ABA) rather than IAA. Doubt was cast on the popular view that sedimenting starch grains initiate the geotropic response.

Two theoretical papers by I. R. Cowan (Australian National University) and J. H. M. Thornley (National Vegetable Research Station, Littlehampton) gave refreshingly clear ex-

positions of mathematical model building. Their models sought to explain how variations in stomatal aperture might optimise productivity in arid zones and how crop yield might be predicted from measurements. Characteristically, those who felt such models provided a useful insight into their problems reacted favourably, but others felt the degree of abstraction too far removed from current technology to be very useful.

Other topics covered included aspects of carbon metabolism and translocation, cell and apical growth, and rhythms and hormonal integration.

Although the papers varied considerably in the viewpoint which was taken this symposium provided something for everyone. The organisers are to be congratulated for providing an invaluable platform which was educational and extremely enjoyable for all concerned, and the published text is awaited eagerly. □

Miraculous peat?

from F. M. Slater

The 5th International Peat Congress was held in Poznan on September 21-25, 1976.

ONE interesting aspect of the Congress was the claim made for peat and peat preparations as a source of antiviral compounds, and of their use in the treatment of cancers, osteoarthritis and conditions arising from bronchial asthma. W. Adamek of Wroclaw, a medical practitioner, described 13 case histories of people with cancers of the skin, breast or alimentary canal who were treated using a peat extract developed by S. Tolpa (Academy of Agriculture, Wroclaw). Regression of the tumours was evident in ten of the patients when the preparation was administered orally (with intramuscular supplements in the case of breast cancer, rectal supplements for cancer of the lower bowel and poultices in the cases of skin cancer), and three reacted adversely to the treatments.

H. Wrobel and C. Jasiak (Janusz Korczak Hospital, Wroclaw) described how a peat preparation, named only as TK-, was beneficial in the treatment of hyperacidity which usually occurs in patients with bronchial asthma. Fifty patients were treated with the preparation which was administered orally before meals in doses of 30 g three times per day for 3 months. This treatment generally resulted in the complete disappearance or decrease of abdominal discomfort, disappearance

of distention, dull pains and unpleasant taste in mouth. Although the treatment obviously had a beneficial effect the authors admit that the mechanism of the therapeutic action remains unknown.

In much of Europe, unlike Britain, spas, peat baths and indeed the general study of balneology are still very much a feature of the medical scene, and K. Weber and G. Plötner of the German Democratic Republic presented the results of various peat bath therapies in the treatment of rheumatoid arthritis. They concluded that whatever peat consistency they used, all their patients benefited by a reduction in their erythrocyte sedimentation rate.

Although the successful treatment of foot-and mouth disease with peat litter containing humic acids has been demonstrated in the past, little recent work has been done on the antiviral properties of the humic acids of peat. R. Klöcking and M. Sprössig together with T. Klaus-Dieter (Medical Academy, Erfurt), however, presented a paper which demonstrated that ammonium humate possesses antiviral activity against herpes simplex virus types 1 and 2 when used in a concentration between 1 and $10 \mu\text{g ml}^{-1}$. The most humate-sensitive phase of virus multiplication seems to be the adsorption of viruses to the host cells. This report was supplemented by other work from the same institution by J. Witthauer, R. Klöcking, B. Helbig and P. Drabke who reported that the molecular weight of eluted humate was in the range 10^3 – 1.2×10^4 with a peak for ammonium humate at 3.3×10^3 . They also described a sensitive method for the detection of humic acids by means of polyacrylamide gel electrophoresis and staining with 0.2% alcian blue.

Although the congress went on to deal with peatland technology and conservation, it was the uses of peat for environmental protection which caught the imagination of delegates. Peat has been demonstrated to be an effective environmental filter for many substances. B. Illarionovich, G. Alexandrovna and C. Romanovna (Academy of Sciences, Minsk), described how peat's initial and natural affinity for elements such as Cu, Co, Zn, Ni, Ag and Ti can be increased 1.5 to 3-fold by previous oxidation of the peat with nitrogen tetroxide. Z. Rozmej and A. Kwiatkowski (Technical University, Gdansk) demonstrated the importance of brown coal in addition to peat as an ion exchange for metals including Al, Cr and perhaps most importantly U.

D. Asplund, E. Ekman and R. Thun (Technical Research Centre, Espoo) found peat to be effective in the puri-

fication of oily water. Untreated peat had an oil-binding capacity of 1–2 kg oil per kg peat, rising to 3.4 kg oil per kg peat when heat-treated peat was used.

In areas of high environmental value, such places as small camp sites and lay-bys may require a high purity of filtered wastewater such that very low nitrogen and phosphorous levels are present in the effluent. This demand combined with the usually low flow rates in such situations makes the wastewater filtration system described by J. L. Brown and R. S. Farnham (University of Minnesota, St Paul) the ideal answer. The basic design consists of 15 cm of coarse gravel covered by 50 cm of medium to fine sand topped by 30 cm of peat in which a crop cover is grown. The design can be modified by the addition of CaCO_3 to the peat to induce calcium phosphate precipitation or by an additional submerged peat layer to aid denitrification. A circular filter bed of this type 30 m in diameter would be adequate to treat the waste from 80 persons at the rate of 30 cm per week. Not only are effluent nitrogen and phosphorus very low but also, after three summers of operation, removal of total coliform bacteria remains nearly complete. \square

Itinerant-electron magnetism

from E. P. Wohlfarth

A conference on Itinerant-Electron Magnetism was held in Oxford on September 13–15, 1976. It was sponsored by the Magnetism Section of the European Physical Society and the Institute of Physics. The Proceedings will be published next Spring in the *Europhysics Journal Physica B*.

ALTHOUGH the birth of this subject took place some 40 years ago it was not until this September that a full scale conference was devoted to it. The meeting was concerned with the magnetic and related properties of metallic materials as influenced by their energy band structure, the interactions between the itinerant, that is, non-localised electrons, and the proper statistical mechanics determining thermal effects. This combination of influences leads inevitably to such a complex of physical problems that no progress is possible without the most judicious interplay between theory and experiment. Even 40 years turned out to be by no means too long a period to wait for an adequate summary of the status of this subject.

Several conflicting philosophies were

clearly revealed and their full resolution is just as clearly not yet at hand. One of these is concerned with the importance of spin fluctuation effects which T. Moriya (University of Tokyo) described. These effects give rise to serious modifications to the original Stoner model of itinerant magnetism which combines the molecular field approximation with Fermi statistics. D. M. Edwards (Imperial College, London) also discussed the importance of electron correlation effects in transition metals, and J. Hertz (University of Chicago) used an advanced many-body approach to discuss "sloppy" spin waves above the Curie temperature. Expressions of continuing support for the Stoner model in iron, nickel and cobalt were given by M. Shimizu (University of Nagoya). E. P. Wohlfarth (Imperial College, London) felt the case for nickel not proven but that another class of alloys, weak itinerant ferromagnets whose Curie temperature is low, continues to exhibit sufficient evidence for this model, especially where magnetoelastic effects are concerned. New measurements on this aspect were provided by G. Hilscher (Technical University of Vienna) and K. H. J. Buschow (Philips Research Laboratories, Eindhoven). On the other hand S. Ogawa (Electrotechnical Laboratory, Tokyo) and Y. Masuda (University of Nagoya) produced experimental evidence for the importance of spin fluctuations in describing dynamic properties of weak itinerant ferromagnets. M. Brodsky (Argonne National Laboratory) described evidence for related many-body effects in the specific heat of some actinide compounds.

A popular field of research in the subject concerns the spin polarisation of electrons emitted from ferromagnetic metals and alloys. R. Meservey (National Magnet Laboratory, MIT) described measurements showing that the polarisation of electrons tunnelling from alloys follows the static magnetisation closely. W. Eib (ETH, Zürich) showed new photo-emission data for single crystal nickel specimens which showed an expected low energy sign reversal. A feeling thus arose, perhaps somewhat dangerously, that the ground state of nickel is fully understood using a simple band approach. M. Campagna (Bell Laboratories) also gave supporting evidence.

C. G. Windsor (Harwell) and Y. Ishikawa (Tohoku University, Sendai) described old and new data obtained by the most fruitful of all experimental techniques, involving neutron scattering. Among other results such measurements give valuable information on the properties of the elementary excitations in itinerant ferromagnets, the single particle and spin wave excitations.

Both of these were claimed by P. C. Riedi (University of St. Andrews) to have been observed by nuclear magnetic resonance measurements. A. J. Freeman (Northwestern University, Evanston) reported a wealth of calculations of neutron magnetic form factors and related quantities in metals.

Other magnetic materials whose properties may be discussed on the basis of an itinerant electron model include amorphous metals and alloys which were described by G. S. Cargill (IBM, Yorktown Heights) and M. J. Zuckermann (University of Paris, Orsay). R. D. Lowde (Harwell) and W. Young (Queen Mary College, London) gave a theoretical account of antiferromagnetic metals whose properties under stress were described by R. Griessen (Free University, Amsterdam) and E. Fawcett (University of Toronto), concentrating on chromium. More involved results on such materials, involving conductivity transitions, were described by J. M. D. Coey (CNRS, Grenoble).

Whereas the Hubbard Hamiltonian, discussed in its simpler aspects by M. Cyrot (CNRS, Grenoble) is a very use-

ful tool for describing the interactions between the itinerant electrons which are fundamental to the whole range of observed phenomena, an equally basic *sine qua non* are the energy bands themselves, both in pure metals and in alloys. New energy band calculations in nickel and iron were described by J. Callaway (Louisiana State University, Baton Rouge) who was able to estimate the parameter of the Hubbard Hamiltonian. Similar results were also obtained by O. K. Andersen (Technical University, Lyngby) and O. Gunnarsson (Institute of Theoretical Physics, Gothenburg). The approaches of these three talks present a new era of accuracy in band calculations as relevant to the magnetism of metals. J. Kanamori (University of Osaka), on the other hand, summarised the results of the coherent potential approximation in alloy calculations.

In the introduction to the Conference mention was made of the giants of the subject who were unable to be present. One of these, J. C. Slater, had only recently died and the Conference remembered his pioneering work with humility. □

sence of histone, it was found that only 50% of reticulocyte NHPs bind to DNA in the absence of histone and NaCl, suggesting that some NHPs require histones for complete reassociation. While of the 50% of the NHPs which do bind in the absence of histone, the majority elute at 0.15 M NaCl, a significant fraction elutes only at lower NaCl concentrations at which the bulk of the histones do not bind to DNA. In general the NHPs which bind to free DNA have low molecular weights and do not show species specificity when compared to NHPs from Ehrlich ascites tumour chromatin.

Thus Gadski and Chae have begun to survey a range of characteristics of the individual proteins which comprise the NHPs of chromatin. Knowing the number of individual NHP species, their molecular weights, their relative concentrations and the conditions under which they will bind to DNA and/or to a DNA-histone complex will give clues as to the function of specific NHPs. Comparison of binding patterns such as presented here with those of the NHPs of other species might suggest which of the DNA-binding classes of NHPs are species specific and which thus might be likely candidates for key roles in the regulation of transcription. Obviously the type of experiment which Gadski and Chae present offers little information as to the specific

Non-histone proteins

from Carol K. Klukas

THE complex composition of chromatin and the intricate interactions of DNA with histones and non-histone proteins (NHPs) which define its structure are of great interest to many biochemists today because these interactions are centrally involved in the system of control of eukaryotic genome expression. The innate complexity of chromatin structure has necessitated division of the general problem into smaller and more approachable segments. Isolated histones, for example, have been studied at great length including the sequencing of the individual proteins and more recently the analysis of the interactions of histones with each other and with DNA to form nucleosomes. Because the number of different histones is quite small and because their sequences have been highly conserved through evolution, the analysis of histones has been a relatively straightforward and manageable task. The non-histone proteins contained in chromatin, however, include many more individual species, which are each present in much lower quantities than the histones, and which, moreover, probably differ considerably with species and with tissue. From numerous *in vitro* transcription and reconstitution experiments it seems quite clear that the function of at least one or a few of the non-histone proteins is to direct exactly which of the genes are to be

transcribed from the DNA in a particular tissue at a specific time. The elucidation of how they interact with each other and with the histones and DNA to accomplish this task will be very difficult to be sure; however work in this direction has already begun as illustrated by a recent paper in *Biochemistry* (Gadski and Chae, *Biochemistry*, **15**, 3812; 1976).

In this paper Gadski and Chae present their studies of erythrocyte and reticulocyte chromatin dissociated in 2 M NaCl-5 M urea. The resultant reconstituted chromatin was analysed on acid-urea-polyacrylamide gels to determine which histones had bound to the DNA, as well as on SDS-polyacrylamide gels to determine which of the NHPs had bound. Using this assay system Gadski and Chae have found that at least one major high molecular weight NHP and two minor smaller molecular weight proteins remain associated with DNA in the 2 M NaCl-5 M urea dissociation conditions. Various other NHPs associate with DNA before, during and after the association of histones with DNA as the NaCl concentration is dropped. This indicates that the NHPs include protein species with a wide range of binding characteristics.

In similar experiments in which NHPs and DNA bound to cellulose were allowed to reassociate in the ab-

A hundred years ago

IN the very interesting Address delivered by Sir C. Wyville Thomson, at Glasgow, on the *Challenger* expedition, while referring to the "red clay" deposit so general over the deepest parts of the Atlantic and North Pacific, the remarkable fact is mentioned that the clay contains numerous nodules of peroxide of manganese, which in some places are found in great quantity. The Address goes on to say:—"This is a phenomenon which we are as yet unable to explain, and I do not know that there is any analogous instance in any of the older formations" (*NATURE*, vol. xiv, p. 494).

A GERMAN paper describes a dreadful fight between two Polar bears, male and female, in the Cologne Zoological Gardens. After a fierce struggle the female became exhausted, and was dragged by the male into the water basin in the den, and held down till life was quite extinct. He then pulled her out and dragged the body for a considerable time round the den. From *Nature*, **15**, November 16, 57, 70; 1876.

mechanism whereby the NHPs participate in control of genome expression, however, their results do certainly suggest some generalities about NHPs; such as that at least some of the NHPs must bind to the chromatin complex in cooperation with histones. Certainly many more studies must be performed using chromatin from different tissues and species before systematic comparisons among them all can be made. Such comparisons it is hoped, will begin to give clues as to which of the NHPs are responsible for control of the specificity of transcription and how each of them accomplishes this function. □

European geophysics

from a Correspondent

AFTER conferences in Zurich (1973) and Trieste (1974) the European Geophysical Society held its third meeting at the Free University of Amsterdam on September 7–10.

THE meeting attracted participants from both eastern and western Europe and the United States including a significant proportion of graduate students and 'younger' research workers.

In an effort to provide a forum for as many geophysical interests as possible, and to give the meeting a more open character, the scientific organisation was changed this year into a divided programme of eight convened symposia (containing some invited contributions) and seven more loosely structured subject sessions arranged on the basis of submitted abstracts.

In the symposium on Reliability of Palaeomagnetism: Criteria, Methods and Error Estimation several authors emphasised the importance of multi-component magnetisations, and there were few contributions which treated the problem from a purely rock magnetic standpoint. Among the most notable of these was that by H. Soffel (University of Munich) who showed the domain structure in pyrrhotite from a Devonian diabase. Using the Bitter technique and with the help of a Super-8 movie, Soffel demonstrated lamellae-shaped domains, the absence of closure domains, pseudo-single domain effects and the phenomena of domain wall pinning and magnetic viscosity. Soffel later used the same technique to justify the use of basalts with low Curie temperatures ($<70^{\circ}\text{C}$) in palaeomagnetic studies. Domain structure studies at different temperatures showed that the

largest titanomagnetite grains had the lowest Curie temperatures. Smaller grains and some grain margins had the highest Curie temperatures and it was these which carried the magnetically hard part of the natural remanent magnetisation.

The problem of multicomponent magnetisation in basaltic rocks was considered by R. Løvlie and K. M. Storetvedt (University of Bergen) with R. L. Wilson (University of Liverpool). Løvlie, in a paper read by Storetvedt, discussed Tertiary basalts from the Faeroes and questioned the general validity of the baked contact test for identifying primary magnetisations, suggesting that the Middle and Upper Lava Series could have been completely remagnetised in the Middle–Upper Tertiary times. In the Skye lavas Storetvedt showed that the large range of inclinations is due to a composite palaeomagnetic record and made the point that the original direction of magnetisation isolated in laboratory treatments is not always the most significant.

Many of the papers on sediments in the same symposium carried a similar theme. R. Thompson (University of Edinburgh) reviewed the criteria for assessing the reliability of palaeomagnetic data derived from unconsolidated sediments. He stressed the need for careful consideration of the physical and chemical factors which might affect the intrinsic magnetic character of unconsolidated sediments and emphasised the importance of chemical remanence. Thompson later went on to establish minimum criteria for establishing geomagnetic excursions by example from two cores from southern Sweden which spanned the time of the supposed Laschamp event (13,000–10,000 BP). Thompson showed that low inclinations and anomalous declinations were not repeatable between these cores and indicated that they were due to inwashed sands and older material.

Doubts were also cast on the validity of the intensity minima of the geomagnetic field during polarity transitions. Løvlie developed a model based on redeposition experiments of deep sea sediments which is compatible with a zone of gradual consolidation in which alignment and immobilisation depend on the grain size distribution of the magnetic particles. The implication is that the intensity minima associated with polarity transitions are due to some intrinsic character of the sediment rather than a weakening of the intensity of the geomagnetic field.

A symposium on The Sources of Marine Magnetic Anomalies: Nature and Location showed that interpretations regarding the source of marine magnetic anomalies are being re-

thought rapidly. The notion that the anomalies reside in the oceanic basalts which form oceanic layer 2A would seem to be an oversimplification and a much thicker source layer (perhaps the whole crust) seems likely. C. Harrison (University of Miami) and N. Watkins (University of Rhode Island) demonstrated that holes drilled into the Atlantic oceanic basement to a depth of a few tens of metres do not reveal consistent magnetisation. In particular there is much variation in inclination and the implication is that the source of the anomaly is distributed throughout the oceanic crust. W. Lowrie (University of Zurich) came to a similar conclusion from the Deep Sea Drilling Project. Results from 55 sites have inclinations which do not agree with expected values; also NRM intensity shows large between-site scatter and Lowrie concluded that layer 2A shows much lateral as well as vertical inhomogeneity.

Interesting results obtained by French research workers in Antarctica were described in the environmental geochemistry session. C. Boutron (University of Grenoble) presented data, collected at South Pole station, on heavy metal concentrations in snow samples which covered the period 1950–1974. He showed how concentrations of lead and copper had increased by factors of 2 and 3 respectively over this period (though no systematic trend was found for cadmium). While the results were in general agreement with aerosol data, the author stressed how dependent the enrichment determinations were on the reliability of the reference values adopted for the mean crustal composition. Caution was also expressed against attributing the high measured enrichments to global pollution alone; the influence of local sources requires full investigation also.

Some of the stabilising effects of partial melting of upwelling mantle material at ocean ridges were considered by E. R. Oxburgh and E. M. Parmentier (Oxford University) in a symposium on Kinematics and Dynamics of Plate Tectonics. By describing the sequence in which mantle material becomes depleted by removal of high density garnet, they were able to show that density differences between the starting material and the final residue were at least of the same order as density differences arising from the typical temperature variations which drive convective motions in the mantle. Although not proposing an alternative to the thermal convection mechanism for plate motion, Oxburgh pointed out that compositional density differences can be expected to have an important modifying role in determining the form of mantle circulation. □

review article

Observational constraints on the masses of neutron stars

P. C. Joss* and S. A. Rappaport*

Direct information on the masses of five neutron stars is available at present. The mass estimates do not yet place any serious constraints on nuclear physics theory. However, if all five neutron stars have about the same mass, then the allowed mass range is quite narrow (~ 1.4 – $1.8M_{\odot}$) and is consistent with conventional pictures of neutron-star formation.

THE masses of neutron stars are of considerable theoretical interest, for two main reasons.

First, the demonstrated existence of a high mass neutron star would place constraints on nuclear physics, gravitation theory, or both. Nuclear physics in principle determines the equation of state of matter at extremely high densities. For a specific theory of gravity, the equation of state, in turn, governs the limiting mass of a stable neutron star. Following the epochal paper by Oppenheimer and Volkoff¹, much effort has been expended in estimating this limiting mass. When used to extrapolate the equation of state to densities well in excess of nuclear-matter densities ($\sim 2 \times 10^{14} \text{ g cm}^{-3}$), conventional theories of many-body nuclear physics, in conjunction with the theory of general relativity, predict a limiting mass in the range 1.7 – $2.7M_{\odot}$ (refs 2–4). However, a limiting mass as large as ~ 3 – $5M_{\odot}$ is still consistent with all direct experimental nuclear and high energy physics data^{2,5,6}. It has been shown^{7,8} that differential rotation cannot increase the limiting mass by more than $\sim 30\%$. However, if one modifies the theory of gravity, a stable neutron-star model of much larger mass can be constructed^{8,9}.

Second, in the most widely accepted picture of stellar evolution^{10,11}, a highly evolved massive star develops a degenerate core that grows by accretion of mass from the surrounding stellar envelope. As the mass of the core approaches the Chandrasekhar limiting mass ($\sim 1.4M_{\odot}$) appropriate to its composition, a thermonuclear runaway and/or dynamical collapse ensues, presumably leading to a supernova event and, in at least some cases, the production of a neutron-star remnant. Although there are many remaining theoretical uncertainties (see, for example, refs. 12 and 13), a neutron star that is formed in this manner may well have a mass comparable to that of the core of the progenitor star (that is, $\sim 1.4M_{\odot}$). If a large fraction of observed neutron stars are actually found to have masses near this value, then substantial support for conventional pictures of advanced stellar evolution and neutron-star formation would have been obtained.

In the past few years, significant empirical information on the masses of several neutron stars has become available for the first time. These neutron stars are all in binary systems, and the mass information is derived from the observed interactions between the neutron stars and their companions. In this paper, we describe the present state of empirical knowledge of neutron star masses and discuss the theoretical implications of this information.

Binary systems containing neutron stars

At present, there are four known binary systems that contain X-ray pulsars and one system that contains a radio pulsar. (Six other X-ray pulsars have been discovered^{14–17} and these objects are also likely to be in binary systems, but neither conclusive evidence of binary membership nor useful orbital information is yet available.) For three of the binary pulsars, the pulse period (P) is well under 2 s, which is too short to be a plausible surface rotation period of a white dwarf (see for example, ref. 18) or the pulse period of a white dwarf that is vibrating in its fundamental mode¹⁹. Moreover, the existence of periodic pulsations rules out the possibility that any of these objects is a black hole. Thus, all three of these pulsars are almost certainly neutron stars. The remaining two objects (the X-ray pulsars 3U0900–40 (ref. 20) and Cen X-3 (refs 21, 22)) are also almost certain to be neutron stars, but the reasons for this conclusion are somewhat more complex and will be explained below.

Of course, it is also very likely that the remaining radio pulsars are all neutron stars. However, the neutron stars in binary systems are unique in that it is possible to place significant constraints on their masses that are independent of any theoretical assumptions concerning the equation of state of matter at high densities.

The existence of an object that emits periodic pulsations in a binary system enables one to measure the period, P_{orb} , and projected semimajor axis, a_p , of the orbit of the pulsar, from which one can infer the mass function:

$$f(M) = \frac{4\pi^2 (a_p \sin i)^3}{GP_{\text{orb}}^2} = \frac{M_c^3 \sin^3 i}{(M_p + M_c)^2}$$

where i is the inclination of the orbital plane with respect to the plane of the sky, M_p is the pulsar (neutron star) mass, and M_c is the mass of the companion star. To derive useful constraints on M_p , it is necessary to obtain independent information concerning the values of M_c , i , or both. The nature of this information is different for each of the five binary systems of interest.

In the following paragraphs, we describe the relevant observational properties of each of the five binary systems, the type of information used to constrain the value of M_p , and the indicated range of allowable values of M_p . Quoted error bars and confidence limits are taken from the original observational work, and wherever possible we state the level of significance. In all cases, the final limits on M_p are not formal confidence limits, but are rather the minimum and maximum values that are consistent with all of the available observational information.

3U0900–40 is an eclipsing binary system, as are all four

*Alfred P. Sloan Research Fellows. Address: Institute for Advanced Study, Princeton, New Jersey 08540; permanent address: Department of Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

X-ray pulsar binaries, with $P_{\text{orb}} \approx 8.966$ d (ref. 23). The binary is composed of an X-ray star and an optical companion, HD77581 (ref. 24), that has been classified as B0.51b (ref. 25). It has been discovered²⁰ that the X-ray star is a long period pulsar, with $P \approx 283$ s, $a_p \sin i = 111.4 \pm 3.3$ (1 σ) light s, and $f(M) = 18.46 \pm 0.79$ (1 σ) M_\odot (ref. 26). The orbit was also found to be slightly eccentric, with eccentricity $e \approx 0.13$ (ref. 26).

The apparent brightness of HD77581 ($V \approx 6.9$; ref. 27) makes it relatively easy to measure the optical radial velocity variations due to orbital motion. Hence, this system can, in effect, be treated as a double-line 'spectroscopic' binary. The optical radial velocities can be used to derive the projected semimajor axis ($a_c \sin i$) of the companion star, and one thereby obtains a second relation for the stellar masses in terms of measured quantities

$$M_p(a_p \sin i) = M_c(a_c \sin i)$$

Unfortunately, there are large non-statistical fluctuations in the optical radial velocities, probably caused by variations in the strong stellar wind from HD77581 (ref. 23) or other mass flow within the binary system. The smallest value of $a_c \sin i$ that has appeared in the literature is based on an analysis²⁶ of the most recent optical data obtained by van Paradijs *et al.*²⁸: $a_c \sin i = 7.79 \pm 0.74$ (1 σ) light s. On the other hand, the orbital fit to optical data that gives the largest value of $a_c \sin i$ and is still consistent with the known orbital eccentricity (which was recently determined accurately from X-ray data)²⁶ is solution 1a by Wallerstein²⁹: $a_c \sin i \approx 15.1$ light s.

The final constraints that one uses are the limits on $\sin i$ that can be derived from analysis of the ellipsoidal light variations of the companion star (which are caused by its rotation and its tidal distortion by the X-ray star) and the X-ray eclipse duration (which is also affected by the rotational and tidal distortion). The observed value of the eclipse duration is 1.90 ± 0.05 d (ref. 30). The most recent analyses^{31,32} indicate that $70^\circ \lesssim i \lesssim 90^\circ$ if $a_c \sin i \approx 7.8$ light s, and $80^\circ \lesssim i \lesssim 90^\circ$ if $a_c \sin i \approx 15.1$ light s. We note that one of these analyses³¹ correctly gave the range of acceptable values of $a_p \sin i$ before the measurement of this parameter from X-ray data, which lends credence to the standard theoretical picture of X-ray binary systems that is used in this method of analysis and to the results of similar analyses of other X-ray binaries described below.

Small values of $a_c \sin i$ and large values of i correspond to small values of M_p , and vice versa. Combining the measured mass function with the probable lower and upper limits on i and $a_c \sin i$, we obtain for the range of allowable values of M_p

$$1.4M_\odot \lesssim M_p \lesssim 3.5M_\odot$$

M_p is probably greater than the maximum stable mass for a white dwarf in the absence of differential rotation (internal rotation periods $\lesssim 10$ s; surface rotation period ≈ 283 s), and such strong differential rotation would probably induce a dynamical instability (compare refs 18, 33). For these reasons it has been concluded^{20,26} that this slow pulsar, as well as the fast pulsars discussed below, is almost certainly a neutron star.

The X-ray source **Cen X-3**, with $P \approx 4.842$ s, was the first X-ray pulsar to be discovered^{21,22}. The highly circular orbit ($e \lesssim 0.003$ (ref. 34)) of the X-ray star has $P_{\text{orb}} \approx 2.087$ d (ref. 22), $a_p \sin i = 39.73 \pm 0.03$ light s (ref. 22), $f(M) = 15.46 \pm 0.04 M_\odot$ (ref. 22), and an X-ray eclipse duration of 0.45 ± 0.02 d (refs 35, 36). A B0II star was established by Krzeminski³⁷ as the optical companion. The pulse period is not quite short enough to rule out a white dwarf model for this X-ray star, but its very high X-ray luminosity ($\sim 3 \times 10^{37}$ erg s⁻¹ (ref. 38)) strongly rules against white dwarf models³⁹. Hence, this object is again almost certain to be a neutron star.

When the measured ellipsoidal light variations^{37,40} of Krzeminski's star and the X-ray eclipse duration are incorporated into theoretical models for the tidal and rotational distortion of the optical star^{36,41,42}, the mass ratio ($q = M_p/M_c$) and i can be estimated: $0.04 \lesssim q \lesssim 0.09$ and $74^\circ \lesssim i \lesssim 90^\circ$. The acceptable values of q and i are strongly correlated. When these

constraints are combined with the measured mass function, limits on M_p are obtained^{36,41,42}

$$0.6M_\odot \lesssim M_p \lesssim 1.8M_\odot$$

Situated in the Small Magellanic Cloud, **SMC X-1** is the only extragalactic X-ray source known to be in a binary system⁴³. The optical companion, Sk160 (refs 44, 45), is of spectral type BOI (ref. 44). Recently, pulsations from the X-ray star with $P \approx 0.715$ s were discovered⁴⁶, followed shortly thereafter by a measurement of the orbital Doppler curve of the pulsar⁴⁷. The nearly circular orbit ($e \lesssim 0.04$ (ref. 47)) has $P_{\text{orb}} \approx 3.892$ d (ref. 48), $a_p \sin i = 53.83 \pm 0.35$ (1 σ) light s (ref. 47), $f(M) = 11.05 \pm 0.22$ (1 σ) M_\odot (ref. 47), and an X-ray eclipse duration of 0.60 ± 0.03 d (refs 43, 47, 48).

The projected orbital velocity amplitude ($v_c \sin i$) of Sk160 has not been well determined, but the available measurements indicate that $v_c \sin i \sim 40$ km s⁻¹ (ref. 49), corresponding to $a_c \sin i = (P_{\text{orb}}/2\pi) v_c \sin i \sim 7$ light s. Taking 20 and 60 km s⁻¹ as probable lower and upper limits on $v_c \sin i$, and using the observed X-ray eclipse duration in conjunction with theoretical models of the tidal and rotational distortion of the optical star to place constraints on the permissible values of i at each value of q , one obtains⁴⁷

$$1.1M_\odot \lesssim M_p \lesssim 4.0M_\odot$$

The ellipsoidal light variations of Sk160 have been measured⁵⁰⁻⁵⁴ but their analysis is complicated by the effect of X-ray heating of the optical star, which is appreciable in this system. Estimates of q and i based on such analyses^{55,56} are consistent with those obtained from the considerations described in the preceding paragraph.

Hercules X-1 is unique among all X-ray binaries in that the companion star, HZ Herculis⁵⁷⁻⁶⁰, is known to be of relatively late spectral type. When the X-ray star is in eclipse, the spectral type is late A or early F; but when the X-ray star is visible, the optical luminosity increases by a factor of ~ 4 and the spectral type changes to B (refs 58, 61-65). These optical variations are apparently caused by the strong heating of one face of the optical companion by the X-ray star. Unfortunately, the uneven surface brightness greatly complicates the extraction of mass information from the measured optical radial velocities, since these velocities are consequently affected strongly by the stellar rotation as well as the orbital motion^{62,66}.

The strong X-ray heating also precludes observation of the ellipsoidal light variations at the present time. However, from photographic plates dating back to 1890, it has been found⁶⁷ that the X-ray star apparently ceases its emission for extended periods lasting months to years, during which HZ Her displays ellipsoidal variations. The number and quality of the old photographic plates are insufficient to place useful constraints on q and i (refs 42, 66), but observations of future inactive-state ellipsoidal variations should be very powerful in this regard.

The binary system has $P_{\text{orb}} \approx 1.700$ d (refs 68, 69), a nearly circular orbit ($e \lesssim 0.002$; ref 34) and an X-ray eclipse duration of 0.24 ± 0.01 d (ref. 69), and the X-ray pulsar has $P \approx 1.238$ s (ref. 68, 69), $a_p \sin i = 13.18 \pm 0.03$ light s (ref. 68), and $f(M) = 0.85 \pm 0.01 M_\odot$ (ref. 88). Estimates of M_p have been made⁶⁶ using this eclipse duration and mass function together with theoretical models of the tidal and rotational distortion of HZ Her. One obtains $q \lesssim 0.7$, no meaningful constraint on i , and

$$M_p \lesssim 1.8M_\odot$$

Other methods of estimation of M_p give values that are consistent with this range but are unable, at present, to constrain more strictly the range of allowable values^{42,66}.

Recently, another independent estimate of M_p has been carried out⁷⁰, based on an analysis of extensive observations of 1.24-s optical pulsations that are occasionally seen from the system and apparently result from the reprocessing of pulsed X rays near the surface of HZ Her. In the context of the

assumed model, it was found that HZ Her must fill its critical lobe and a value of $M_p = 1.30 \pm 0.14 M_\odot$ was thereby obtained. However, it is uncertain at present how sensitive this result is to some of the assumptions of the model, including the assumption that HZ Her is in synchronous rotation and the implicit assumption that there is no strong orbital-phase-dependent obscuration of the optical pulsations by other matter within the binary system. At least one further analysis of the optical pulsations is being carried out at present (T. Chester, personal communication).

PSR1913+16 is the only radio pulsar (of ~ 150) that is known to be in a binary system. The pulsar, which has $P \approx 0.0590$ s, was found to be in an eccentric binary orbit with $e \approx 0.62$, $P_{\text{orb}} \approx 0.3230$ d, $a_p \sin i \approx 2.336$ light s, and $f(M) \approx 0.1313 M_\odot$ (refs 71, 72). No eclipses are observed in this system⁷¹.

During subsequent observations over the course of about a year, it was discovered that the longitude of periastron (related to the angle between the view direction from the earth to the star and the line of closest approach from the star to its companion) was changing at a rate of $\dot{\omega} = 4.22 \pm 0.04^\circ \text{ yr}^{-1}$ (ref. 72). This effect, known as apsidal motion, can be completely accounted for by general relativity. However, it is possible, depending on the radius and other properties of the unseen companion, that some or all of the apsidal motion could be caused by a tidally or rotationally induced quadrupole moment of the companion^{73,74}. Under the assumption that the observed apsidal motion is entirely a general relativistic effect, the measured mass function can be combined with the general relativistic expression for this effect to obtain a relation for the sum of the two stellar masses^{72,75}

$$M_p + M_c = 2.83 M_\odot$$

If some of the apsidal motion is due to a tidally induced quadrupole moment, or to a rotationally induced quadrupole moment with the axis of rotation at least $\sim 35^\circ$ out of the orbital plane⁷⁵, then $M_p + M_c$ must be less than this value.

A normal main-sequence star would induce a value of $\dot{\omega}$ much larger than that observed^{73,76,77}. The companion could be a white dwarf, neutron star, or black hole, or it might be a peculiar star that is nondegenerate but nonetheless has an anomalously small radius ($\lesssim 0.1 R_\odot$). Many theoretical studies of such stars have appeared in the literature (see, for example, refs 78–81).

Combining the sum of the masses with the measured mass function, one obtains constraints on the allowable values of M_p (ref. 75). If the companion is a white dwarf, then its mass must be less than $\sim 1.4 M_\odot$ (unless it is undergoing rapid rotation) and this yields $1.4 M_\odot \lesssim M_p \lesssim 1.9 M_\odot$. In the case where the unseen companion is also a neutron star, then $M_p \lesssim 1.9 M_\odot$ and the mass of the companion neutron star is also constrained: $1.0 M_\odot \lesssim M_c \lesssim 2.9 M_\odot$. Moreover, at least one of the two neutron stars must have a mass $\gtrsim 1.4 M_\odot$. For other possible types of companion stars, all that can be determined is that $M_p \lesssim 1.9 M_\odot$.

In summary, as long as the theory of general relativity is correct, one obtains:

$1.4 M_\odot \lesssim M_p \lesssim 1.9 M_\odot$ for a normal white-dwarf companion;
 $M_p \lesssim 1.9 M_\odot$ for other types of companion.

Summary and conclusions

At present, there are five X-ray and radio pulsars that are very probably neutron stars and that are contained within binary systems. The periodic pulsations from these pulsars and their interactions with their respective companion stars enable constraints to be placed on the neutron-star masses. The available constraints are summarised in Fig. 1.

It is apparent that these mass estimates are all still entirely consistent with the predictions of nuclear physics. None of these neutron stars need have a mass greater than $\sim 1.4 M_\odot$, while a minimum mass of $\sim 1.8 M_\odot$ would be needed to exclude at least

Fig. 1 Empirical constraints on the masses of neutron stars. For each of the five binary systems containing neutron stars, the bar denotes the range of masses that is consistent with all of the available observational information. The close-hatched region ($1.4\text{--}1.8 M_\odot$) represents the range of masses consistent with all five neutron stars. The open-hatched region ($1.7\text{--}2.7 M_\odot$) indicates the range of limiting neutron-star masses predicted by present conventional theories of many-body nuclear physics (see text).

some of the equations of state that have been derived^{2–4} from present conventional theories of many-body nuclear physics.

On the other hand, if one hypothesises that most or all neutron stars have about the same mass, then the range of masses that are allowable for all five cases is quite narrow ($\sim 1.4\text{--}1.8 M_\odot$; Fig. 1). It is noteworthy that this is consistent with the range of masses that one might expect if neutron stars are formed in supernova events resulting from the collapse of the degenerate cores of highly evolved stars.

For 3U0900–40, Cen X-3 and SMC X-1, significant refinement of the neutron-star mass estimates must probably await extensive new observations of the optical radial velocities and an improved theoretical understanding of systematic fluctuations in the radial velocities and other measured properties of the companion stars. In the case of Her X-1, further analysis of the optical pulsations is promising as an improved method of mass estimation. In addition, when Her X-1 enters another extended X-ray inactive state, measurements of the radial velocities and ellipsoidal light variations of the optical companion should greatly refine the mass estimate of the neutron star. Further refinements of the neutron-star mass estimate of PSR1913+16 will be possible when additional mass-dependent relativistic effects (gravitational redshift and second-order Doppler shift) can be separated from the first-order orbital Doppler shift; this will occur when the longitude of periastron advances through an appreciable angle from its present value, which will require $\gtrsim 5$ yr (ref. 82).

Several other X-ray pulsars have recently been discovered and it seems likely that most or all of these objects are in binary systems. For at least two of these objects, 3U0352+30 and A0535+26, there is already some direct observational evidence of binary membership^{83–85}. As additional pulsars are discovered and shown to be in binary systems, and as constraints on their masses are developed, the improved observational statistics will constitute a further refinement in empirical information on neutron-star masses.

We thank Y. Avni, J. N. Bahcall, S. Hayakawa and J. I. Katz for helpful discussions, and Dr Carl Kaysen for his hospitality at the Institute for Advanced Study. This work was supported in part by NASA.

Polarisation detection at radio wavelengths in three spiral galaxies

A. Segalovitz & W. W. Shane

Sterrewacht, Leiden 2405, The Netherlands

A. G. de Bruyn

Hale Observatories, Pasadena, California 91101

Polarisation at radio wavelengths has been measured in the disk radiation of M51, M81 and M31 using the Westerbork Synthesis Radio Telescope. The magnetic field of M51, as implied by the polarisation vector map, is oriented preferentially in the tangential direction. The intrinsic polarisation of the disk radiation of M51 is estimated to be, on average, 12%, corresponding to an anisotropy (or degree of uniformity) in the magnetic field of 14% with scale length ≤ 3 kpc. A 7% lower limit is set on the disk polarised radiation of M81, but on some parts of the disk of M31 it reaches 20%.

WE have constructed a model which is especially suitable for the interpretation of radio polarisation measurements on the disks of spiral galaxies—polarisation is evidence for anisotropy in the magnetic field. Models which relate, under various conditions of field topology and object geometry, the observed linear polarisation and a measure of the anisotropy of the field have been constructed by Korchakov and Syrovatskii¹ and by Burn², but neither of these models is quite applicable to the case we discuss, although, for the conditions of interest, the results do not seem to be very model dependent.

We shall consider a region in a disk galaxy defined, of necessity, by the angular resolution of the observations (see Table 1). This region is thought of as divided into volume elements of equal size, so small that the magnetic field within

each element is essentially homogeneous and unidirectional. We now represent the distribution of magnetic fields by supposing that a fraction f of the volume elements contains a field with a single uniform spatial orientation (\mathbf{u}), while the orientation of the field in the remaining elements is randomly distributed (\mathbf{r}). We further assume that the distributions of relativistic electron densities and magnetic field strengths are the same in both components. If this is not the case, then the contributions to the observed intensity from the two components must be weighted according to their mean volume emissivities, $\langle n_{\text{rel}} H^{(\gamma+1)/2} \rangle$, where γ is the electron energy spectral index. The fraction f is a measure of the anisotropy of the magnetic field within the resolution element. Using standard expressions³, it is easily shown that under the above conditions the degree of intrinsic polarisation is

$$\rho = \frac{3\gamma+3}{3\gamma+7} \left[1 + \frac{(1-f)\pi^{1/2}\Gamma[(\gamma+5)/4]}{2f(\sin \theta)^{(\gamma+1)/2}\Gamma[(\gamma+7)/4]} \right]^{-1} \quad (1)$$

where θ is the angle between the line of sight and $\hat{\mathbf{u}}$.

The observations described in this paper indicate that the orientation of \mathbf{u} , in M51 at any rate, is largely tangential in the galactic plane. We shall make only the more general assumption that \mathbf{u} is parallel to the disk and, taken over the galaxy as a whole, has no further preferential orientation with respect to

and i is the angle between the plane of the sky and the galactic plane. In Fig. 1, $\langle \rho \rangle$ is shown as a function of f for $\gamma = 2.5$ and for two values of i .

Two points should be stressed: first, the degree of anisotropy, f , refers to the angular resolution element. We expect that it will increase with decreasing beam size; second, no account has been taken of depolarisation from either differential Faraday rotation along the line of sight or from the changes in rotation measure with position within a resolution element. This will often be of importance, particularly in regions of high density, and thus the value of the anisotropy derived by this method will be a lower limit. At $\lambda = 6$ cm, however (see below), we do not expect Faraday depolarisation to be very effective.

Observations and results

The WSRT has been used to observe M51, M81 and M31. The telescope and reduction procedures are described elsewhere⁴⁻⁸. The observational parameters for each of the maps presented hereafter are given in Table 1. The system noise at 1,415 MHz has been reduced by a factor of ~ 2.5 since earlier observations of the same objects with the WSRT.

M51

M51 has been observed with the WSRT at wavelengths of 6, 21 and 49 cm. No polarisation was detected at 49 cm implying

Fig. 1 The average intrinsic degree of polarisation, $\langle \rho \rangle$, plotted as a function of the degree of anisotropy of the magnetic field, f , for electron energy spectral index $\gamma = 2.5$ and two values of the galactic inclination, i .

any fixed direction in space. Clearly a tangential field belongs to this class. In this case, the average degree of polarisation (the scalar sum of the polarised flux from all resolution elements divided by the total flux) is given in equation 1 with $(\sin \theta)^{(\gamma+1)/2}$ replaced by its average value

$$\langle \rho \rangle = \frac{3\gamma+3}{3\gamma+7} \left[1 + \frac{(1-f)\pi^{1/2}\Gamma[(\gamma+5)/4]}{2f\Gamma[(\gamma+7)/4]F(i)} \right]^{-1} \quad (2)$$

where

$$F(i) = \frac{1}{2\pi} \int_0^{2\pi} (1 - \sin^2 i \sin^2 \phi)^{(\gamma+1)/4} d\phi$$

$$= 1 + \sum_{n=1}^{\infty} \frac{(-1)^n}{n! 4^n} \sin^{2n} i \prod_{j=1}^n \frac{(\gamma+5-4j)(2j-1)}{2j} \quad (3)$$

a 3σ upper limit on the polarised brightness temperature of 1.5 K. The beam HPBW of the synthesised 49-cm beam is $56'' \times 76''$, or 2.6×3.6 kpc at an assumed distance of 9.7 Mpc (ref. 9).

Polarisation at 6 cm

The 6-cm observations of M51 have been described elsewhere¹⁰. To increase the signal to noise ratio, the observations were convolved to a $56'' \times 76''$ beam and two maps were produced: an intensity map and a polarisation map (Fig. 2). No appreciable Faraday rotation is expected at such a short wavelength in view of the residual polarisation which is observed at 21 cm (see below). We find it significant, therefore, that at a level $> 2.5\sigma$ ($\sigma = 0.009$ K = 0.9 mJy/beam) the polarisation vectors are generally perpendicular to the spiral arms. This suggests an approximately tangential magnetic field structure. For the Galaxy, such a field configuration is referred to as 'longitudinal' (as opposed to helical). In a recent paper,

Fig. 2 The polarisation vectors of M51 at 6 cm. Vectors whose amplitude is < 2.5 mJy per beam ($\sim 2.5\sigma$) are not drawn. The polarised flux is not corrected for the primary beam attenuation. The primary beam half power circle is drawn as a continuous line.

Spelstra and Brouw (in preparation) argue that a longitudinal field also fits the radio polarization observations of the Galaxy better than a helical field. A tight-helix field configuration would result in a net polarisation along the spiral arm. Such a configuration is ruled out by our results. Our observations do not exclude, though, a very-open-helix field configuration.

The location of the polarised brightness peaks, which range up to ~ 0.05 K, cannot be precisely determined because of the large beam and the weak signal. The percentage polarisation at a few points was computed by dividing the polarised flux by the intensity deduced from the preliminary MPIfR 100-m dish observations of M51 at 4.8 GHz (Wielebinski, private communication). Peaks as high as 20% were found. To determine the average polarisation, we have analysed the distribution of the observed polarised signal to derive the polarised flux (the scalar sum over all resolution elements) corrected statistically for noise. A similar correction has been

applied to all polarisation data. The corrected polarised flux was divided by the total flux within the same region after subtracting a point source of 15 mJy at the nucleus. We find an average polarisation of 12% for radii < 9 kpc (limited by the off-centre instrumental polarisation). Because of the short wavelength, this is probably characteristic of the intrinsic polarisation. This implies an anisotropy of the magnetic field, f_c of 14% on the scale of the resolution element (see Fig. 1; the inclination of M51 is taken to be 35°).

Fig. 3 The polarisation vectors of M51 at 21 cm. Vectors whose amplitudes are < 1 mJy per beam (0.12 K $\approx 2.5\sigma$) are not drawn.

Fig. 4 The polarisation vectors of M81 at 21 cm. Vectors whose amplitudes are < 1.3 mJy per beam (≈ 0.05 K $\approx 3\sigma$) are not drawn. The polarised flux is not corrected for the primary beam attenuation. The polarisation vectors at the western edge of the photograph are related to an external source and may partly arise from instrumental polarisation.

Polarisation at 21 cm

New 21-cm observations of M51 have recently been carried out with the WSRT and will be described elsewhere (Segalovitz, in preparation). Polarisation at the 3σ level ($\sigma = 0.25$ mJy/beam = 0.17 K, determined empirically) was detected at a few scattered locations in the full resolution map ($\text{HPBW}_x \times \text{HPBW}_y = 24'' \times 32'' = 1.1 \times 1.5$ kpc). These peaks did not in general coincide with regions of maximum intensity. They are several times weaker than the polarisation peaks reported previously¹¹.

Fig. 5 Polarisation vectors at 49 cm in two fields in M31. Only amplitudes > 0.34 K ($\approx 5\sigma$) have been plotted. The two circles correspond to a primary beam attenuation of 0.67. With few exceptions, only points lying inside these circles have been plotted. The amplitudes have not been corrected for primary beam attenuation. The polarisation vectors are shown superposed on the 408 MHz total intensity map of Pooley¹⁵. The contour interval is 3 K, corresponding to ~ 1 K at 610 MHz, and the outermost solid curve is the first contour above the nominal zero level. Because of the missing short spacings, the true zero level is uncertain.

Convolving to a $56'' \times 76''$ beam (and thus increasing the signal-to-noise ratio) revealed an extensive distribution of polarised radiation (Fig. 3). The polarised flux over a large part of the Galaxy is at a general level of 1.25 mJy/beam ($= 0.15$ K $\approx 3\sigma$) with peaks at the 0.21-K level. The strongest peak (0.27 K) is associated with an external source E of M51. About half of the area from which the polarised radiation comes is not located at intensity peaks, and for this the resolution is not good enough to make a definite statement. The tendency of the polarisation peaks to be found away from the intensity peaks may result from a less ordered magnetic field or stronger Faraday depolarisation in regions of higher density. The same tendency is found in strong extragalactic radio sources^{12,13}.

In most regions the polarisation vectors are systematically rotated by $\sim 45^\circ$ counterclockwise from the radial direction. Vallée and Kronberg¹⁴ estimate a galactic Faraday rotation in the direction of M51 of -10 ± 15 rad m^{-2} , corresponding to a clockwise rotation of $25 \pm 37^\circ$ at 21 cm. This estimate is not consistent with our data (from comparison of the directions of the 6-cm and 21-cm polarisation vectors). Small-angle deviations of this magnitude from the values predicted from their model are not, however, unexpected. We conclude, from the uniformity of the polarisation vector rotation, that the

systematic Faraday rotation over the resolution element in M51 is at most of comparable magnitude to that estimated in the Galaxy ($\lesssim 20$ rad m^{-2}).

A polarisation map was made by dividing the polarised flux by the total intensity at points where the polarised flux was above the 3σ level. Polarisation peaks reach values of 20%. The average polarisation percentage was derived by dividing the total polarised flux by the total intensity, and was found to be 2.5% for radii < 12 kpc. In this calculation, the flux of the nucleus of M51 (35 mJy) was first subtracted from the total flux. Comparing this value with the apparently intrinsic 12% polarisation, we get a rough estimate of 50 rad m^{-2} for the r.m.s. variations in rotation measure on angular scales much smaller than the resolution element of $56'' \times 76''$ (using the model of Burn²) as compared with the upper limit of 20 rad m^{-2} for large scale fluctuations.

M81 at $\lambda = 21$ cm

The disk of M81 has been observed with the WSRT at 21 cm and at 49 cm. A detailed account of the observations will be given elsewhere (Segalovitz, in preparation). The 49-cm observations show no polarisation > 2.5 K (3σ). The 21-cm

observations convolved to a $1.9' \times 2.1'$ beam (1.8×2 kpc at a distance of 3.2 Mpc) reveal polarisation at a level of 0.05 K to 0.07 K ($\sigma = 0.016$ K = 0.44 mJy per beam) as shown in Fig. 4. The polarisation direction shows no preferential orientation with respect to the azimuthal direction at the few points where it can be determined. Polarisation percentages were derived by dividing the polarised flux by the intensity at some points where a comparatively high polarised flux was detected. The total flux densities were taken from the corresponding intensity map after adding a constant 0.035 K to correct approximately for flux in large scale features which is not detected by the Westerbork telescope. Peaks at the 20% level were found. The average polarisation, derived by dividing the total polarised flux by the total flux after subtracting the nucleus, was 7%. This is considerably higher than for M51. The difference may arise from a smaller Faraday depolarisation in M81 or to a more ordered magnetic field. Taken at face value, the average polarisation of 7% implies that 10% of the magnetic field is ordered (see above and Fig. 1; the inclination of M81 is taken to be 59°). Since Faraday depolarisation inside the Galaxy may be appreciable at 21 cm, the above value should be regarded as a lower limit.

M31 at $\lambda = 49$ cm

A survey of M31 at $\lambda = 49$ cm (see Table 1) has recently been completed. The results will be published in full elsewhere. Examination of the first reductions shows widespread linear polarisation, and a sample of these preliminary results, derived from two fields centred on the major axis and $80'$ on either side of the nucleus, is illustrated in Fig. 5. (Observations of the central region have not yet been fully reduced.) The polarisation vectors have been derived from maps convolved to a $3.6' \times 5.4'$ beam. Only vectors whose amplitudes are $\geq 5\sigma$ (see first note in Table 1) have been plotted. Since the maps of total intensity, whose preparation is much more elaborate on account of the multitude of background sources and the missing short spacings, are not yet available, the polarisation vectors have been superimposed on Pooley's 408-MHz ($\lambda = 73$ cm) map of M31 (ref. 15), which corresponds to approximately the same angular resolution ($4' \times 4'$). Assuming a spectral index of $\alpha = 0.8$ ($S \propto \nu^{-\alpha}$), the contour interval of 3 K on the 408-MHz map would become ~ 1 K on a corresponding map at 610 MHz. Pooley's observations were carried out with the E-vector

of the feed in position angle 90° and, depending on the polarisation, may not be representative of the unpolarised intensities at specific points. Moreover, because of the missing short intervals, the nominal zero may correspond to a true brightness temperature of as much as one contour interval above zero. Three other radio continuum surveys¹⁶⁻¹⁸, at various frequencies and resolutions, all indicate typical brightness temperatures at 49 cm of 1-2 K in these regions.

As in the case of M51, the regions of maximum polarised brightness temperature do not generally coincide with peaks of intensity. While the maximum degree of polarisation is as yet difficult to estimate because of the uncertainty in the zero level, it must amount to several tens of per cent in some regions. Even where the total intensity is relatively high, and correspondingly less uncertain, degrees of polarisation $> 20\%$ are found. A quantitative discussion of these results must, however, await complete reduction of the WSRT observations. Although we might expect quite large Faraday rotation at this frequency, the polarisation vectors show considerable consistency in orientation locally and tend to maintain a constant orientation with respect to the spiral pattern. This suggests that for the regions of M31 where polarisation is detected, the internal Faraday rotation is small compared to M51 and M81.

We thank F. P. Israel for initiating the M31 project and Prof. H. van der Laan for his comments on the manuscript. A.S. thanks The Netherlands Organization for the Advancement of Pure Research (ZWO) for a grant. The Westerbork radio observatory is operated by the Netherlands Foundation for Radio Astronomy with financial support of ZWO.

Cytoskeletal control of surface membrane mobility

Karl-Gösta Sundqvist & Anneka Ehrnst

Departments of Immunology and Virology, Karolinska Institutet, S-104 01 Stockholm, and Department of Immunology, The National Bacteriological Laboratory, S-105 21 Stockholm, Sweden

Cytochalasin B induced redistribution of actin microfilaments into a bulge of the cytoplasm, bringing cell-surface elements to the corresponding surface area. This process was reversible, inhibited by colchicine and enhanced by antibodies to cell-surface antigens.

THE mechanisms responsible for the organisation of the surface membrane¹ and for the mobility of molecules within it are not understood. Long- but not short-range movements of surface antigens²⁻³ are dependent on cell metabolism^{2,9,10}, and inhibited by cytochalasin B (CB)^{7,11}, but not by colchicine¹¹. CB is thought to disrupt a micro-

filament system, containing actomyosin, located below the surface membrane¹². It has therefore been proposed that redistribution of cell surface molecules depends on microfilament activity⁷. In most studies, however, CB has affected membrane mobility only partially^{2,7,10,11} and since the compound has many other effects it may influence membrane mobility in several ways not necessarily involving microfilaments. In addition, CB induces morphological effects on the surface membrane, suggesting that this is one site of action of the compound¹¹.

Microtubular activity has been linked with ligand-induced redistribution (capping) of membrane components in lymphocytes. Capping of immunoglobulin (Ig) on mouse lymphocytes is inhibited by concanavalin A (con A) in

large doses. This inhibition is abolished by colchicine¹⁵⁻¹⁷, which disrupts microtubules. Colchicine also augments the inhibitory effect of CB on capping¹¹. Con A-capping in rabbit ovarian granulosa cells redistributes cytoplasmic microtubules¹⁸.

Here we present evidence for an interaction of cell-surface molecules with the submembranous microfilament system of actomyosin and with the microtubules. In three test systems CB induced a simultaneous reversible redistribution of cell-surface molecules and submembranous actin microfilaments which was counteracted by colchicine.

The cells studied were uninfected, and measles virus (Edmonston strain)-infected heteroploid human lung fibroblasts of the strain Lu 106, mouse L-cells, mouse

lymphocytes, normal human lymphocytes and cells of two human lymphoblastoid cell lines of B cell origin. The antigenic specificities examined included measles virus haemagglutinin (HA), H-2, β_2 -microglobulin (β_2 -m), species antigens (rabbit anti-Lu 106), and Ig on the appropriate cell types.

CB-induced redistribution

Cells were first incubated for 60 min in spinner culture in Eagle's spinner medium supplemented with 5% foetal calf serum (FCS), and then for a further 60 min in the presence of CB ($10 \mu\text{g ml}^{-1}$) unless otherwise stated. Thereafter, to

The cells were incubated for 60 min at 37 °C in Eagle's spinner medium supplemented with 5% FCS before further treatment. The cells, 2×10^6 cells in 1 ml per tube, were then incubated further for 60 min *a*, with no treatment; *b*, in the presence of $10 \mu\text{g ml}^{-1}$ of CB; *c*, in the simultaneous presence of $10 \mu\text{g ml}^{-1}$ of CB and 10^{-2} M of colchicine (colchicine was added 30 min before CB); *d*, in the presence of 10^{-2} M colchicine, and subsequently PFA-fixed before IF-staining. When antibodies were present during the experiment, the cells were reacted with antiserum and conjugate, respectively, for 30 min + 30 min before CB-incubation in 1 ml at 37 °C for 60 min, followed by PFA-fixation. Carrier cells and Lu 106 cells were stained with a rabbit anti-HA serum, a rabbit anti- β_2 -microglobulin serum, a rabbit anti-HeLa serum, a monkey anti HeLa serum, respectively. The L-cells were stained with mouse ACA anti-A/SN and C57BL anti-C3H, respectively.

prevent further redistribution, cells were fixed in 4% paraformaldehyde for 10 min at 4 °C. Finally, antigens were detected on the surface membrane by direct or indirect immunofluorescence staining for 30 min or 30+30 min respectively, at 0-4 °C.

The morphology of Lu 106 and L-cells was affected by CB (Fig 1, Table 1*a*). Cells exposed to CB often formed a bulge which looked like a uropod¹⁹ (Fig. 1). These were most frequent on L-cells, occurring in 80% of cases. In addition, cells treated with CB had 5-15 blebs on the part of the cell carrying the "uropod". β_2 -m and species-specific antisera reacted strongly with the blebs whereas the HA-specific antiserum did not react.

The distribution of antigens at the cell surface was also affected by CB (Fig. 1, Table 1*b*). After incubation in the presence of CB the measles virus HA was present as "caps" on the "uropods" of 40% of infected cells. Control cells incubated without CB, or in the presence of 0.1% DMSO, had a ring-type distribution of HA at the cell surface (Fig. 1). β_2 -m and species antigens of both infected and uninfected Lu 106 cells were also redistributed, less, however, than the HA, and some of these antigens were unaffected.

In CB-treated L-cells, reacted with anti-H-2 sera (ACA anti-A and C57BL anti-C3H/K), cell surface antigens were redistributed in the direction of the "uropod". The extent of redistribution was similar to that of β_2 -m and species antigens on Lu 106 cells. Attempts to induce redistribution of surface antigens by CB in normal lymphocytes of mouse and human origin and in human lymphoblastoid cell lines failed.

Concentrations of CB between 1 and $5 \mu\text{g ml}^{-1}$ were necessary to achieve movement of HA on measles-infected cells, and above $10 \mu\text{g ml}^{-1}$ redistribution reached a plateau (Table 2). While $5 \mu\text{g ml}^{-1}$ was enough for some cap formation of HA, redistribution of β_2 -m required $10 \mu\text{g ml}^{-1}$.

To see whether the induced redistribution of antigens was reversible, CB-treated cells showing redistribution were kept at 37 °C in the absence of CB for various times, and then fixed and reacted with antisera against HA and β_2 -m. After 10 min the number of "uropod"-carrying cells with redistributed surface antigens had decreased from 40 to about 10%. After a further 50 min antigens were again homogeneously distributed.

Tables 1*b* and 3 show the influence of antibody plus colchicine on CB-induced redistribution of cell surface antigens. Measles-virus infected and uninfected Lu 106 cells incubated in the presence of 0.5×10^{-2} M colchicine and CB at $10 \mu\text{g ml}^{-1}$ showed "capping" of β_2 -m in 3% of all cells whereas 15% exposed to CB alone showed "capping". The number of cells exhibiting CB-induced polar distribution of measles virus HA was decreased in the presence of 10^{-2} - 10^{-3} M colchicine (Table 3). Colchicine, however, did not inhibit the formation of blebs. In its presence they were distributed all over the surface membrane (Fig. 1, Table 1*a*). So colchicine seemed to interfere with the movement of blebs to the "uropod".

Simultaneous exposure of infected and uninfected Lu 106 cells to antibody and CB, respectively, increased the frequency, rate and degree of redistribution of surface antigens significantly compared with exposure to each alone

Table 2 Kinetics of redistribution of haemagglutinin (HA)

Treatment with cytochalasin B for 60 min ($\mu\text{g ml}^{-1}$)	A Cells with capped HA (%)	B Treatment with cytochalasin B at 10 $\mu\text{g ml}^{-1}$		C Cells staining with trypan blue after treatment with DMSO 0.1% Cytochalasin B 10 $\mu\text{g ml}^{-1}$		
		Time (min)	Cells with capped HA (%)	Time (min)	No treatment	
0	0	0	4 3	0	4.7 5.6	
1	0	10	13 15			
5	13	30	28 25	60	3.0 4.7	5.3 5.7
10	41	60	44 31			3.0 4.0
				120	3.0 5.7	6.0 7.3
100	41	120	41 43			3.0 5.0

At least 200 cells were counted when percentage of cells was calculated. In B, two individuals calculated one set of values separately (A. E. upper and K.-G. S. lower value). In C, duplicate tubes were set up and the counting performed by one person. The experiments were performed with carrier cells, trypsinised and resuspended in Eagle's spinner medium supplemented with 5% foetal calf serum and kept in 37 °C for 60 min before the beginning of the experiments. Cytochalasin B was dissolved in DMSO and 10 $\mu\text{g ml}^{-1}$ of CB corresponds to 0.1% DMSO. The cells in A and B were fixed with 4% PFA before IF staining with anti-HA serum and examination.

(Table 1b). Thus, at a time when antibody-induced redistribution alone had not yet occurred, in the presence of both CB and antibodies, all antigens studied exhibited pronounced redistribution. This synergistic effect seemed to be independent of which of the reagents, the antibody or CB, were added to the cells first.

Cocapping of surface antigens and microfilaments

The behaviour of submembranous microfilaments of actin in relationship to the redistribution of surface components was examined in uninfected Lu 106 cells. Cells were suspended in 0.034 M sodium citrate, smeared on glass, fixed in dry acetone at -20 °C for 15 min and stained with a human serum containing antibodies to actin.

Before CB treatment, or when treated with DMSO used to dissolve CB, the cells showed virtually continuous IF-staining of their margin and a diffuse staining of the cytoplasm when reacted with anti-actin serum (Fig. 2). In contrast, CB-treated cells exhibited a redistribution of actin to the uropod which was completely reversible within 30 min (Fig. 2). This indicated that the redistribution of actin, and of cell surface antigens described above, were related to each other. To study this further double IF-staining with separate fluorochromes for actin and cell surface antigens was performed. The microfilament system was detected with the human actin antiserum²⁰ and a rhodamine (TRITC)-conjugated sheep anti-human IgG, absorbed with rabbit serum. Cell-surface antigens (β_2 -microglobulin, species-specific antigens) on Lu 106 cells were detected using the appropriate rabbit antisera and a fluorescein (FITC)-conjugated sheep anti-rabbit IgG, absorbed with normal human serum. Before CB treatment, the cells showed continuous IF-staining of their margins with both anti-actin serum (rhodamine) and antisera to surface antigens (fluorescein). On CB-treated cells the rhodamine staining was localised in the cytoplasm corresponding to the "uropod" but in many cells the redistribution was incomplete. To document the results further we took advantage of the synergistic influence of CB and antibody on the redistribution of cell surface molecules. This demonstrated cocapping of surface antigens and actin to the "uropod" (Fig. 3).

The specificity of the anti-actin serum was checked by absorption with purified actin²⁰. This clearly decreased the number of cells that stained with rhodamine as well as the

IF-intensity of the cytoplasm. Anti-actin serum did not stain viable Lu 106 cells.

Mechanisms of cytoskeletal control

Our principal observations were the coincident reversible CB-induced redistribution of microfilaments and cell-surface elements into a bulge of the cytoplasm and the antagonistic and synergistic influence of colchicine and antibodies, respectively, on this process. These results strongly support: (1) the existence of a connection, direct or indirect, between cell surface elements, microfilaments and microtubules; (2) the concept that cytoskeletal structures influence the behaviour of molecules in the plane of the membrane^{15-17,21}; and (3) the concept that microfilaments and microtubules are responsible for the cellular control of membrane mobility and integrity.

It is uncertain, however, whether microfilaments and microtubules antagonise or synergise in provoking and/or preventing membrane mobility. Cytochalasins have been suggested to affect the microfilament system by either disruption¹² or induction of contraction²². Therefore, interpretation of the results in terms of the function of microfilaments and microtubules depends on which of these two effects is favoured. It seems unlikely that the observed effects of CB on the cell surface¹⁴ are responsible for the redistribution of cytoplasmic microfilaments, unless these were exposed on the cell surface. Also it seems unlikely that the redistribution of cell-surface elements, so well correlated to the redistribution of microfilaments, should be due solely to a surface effect of CB. It should be re-

Table 3 Effect of colchicine on CB-induced redistribution of measles virus haemagglutinin

Experiment*	Treatment	Capped cells (%)

Fig. 2 Distribution of actin in uninfected Lu 106 cells *a*, before and *b*, after CB-treatment. Notice the redistribution of IF-staining to uropods.

membered that antibody-induced redistribution of cell surface antigens did not redistribute microfilaments in the absence of CB. Attempts to redistribute microfilaments by capping cell surface antigens in various test systems have failed (K.-G.S., unpublished observations). The reason for this may be that cross linking of cell surface antigens by antibody involves only microfilaments corresponding to the antigens studied, whereas CB redistributes more of the microfilaments, as the present data suggest.

It is interesting in the light of our result that microfilaments in some cell types contract after exposure to CB (ref. 22). Furthermore, cytochalasins induce the formation of knobby protuberances and the migration of these at the surface membrane^{23,24}. The protuberances resemble the blebs we obtained after treatment with CB.

The degree of redistribution varied for different antigenic specificities and cells as reported before with antibody-induced redistribution²⁵⁻²⁷. Measles virus HA exhibited the

greatest redistribution. It was present only on the capped area of the cell surface. HA was absent from the blebs whereas the other specificities were found along the margins of these protrusions. Thus, there may be a correlation between exclusion from blebs and a pronounced tendency to redistribution. This, together with the earlier findings^{7,25-27}, suggests that certain structures in the cell surface membrane, such as HA, are more dependent on the microfilament system than other membrane components.

Our results may seem difficult to reconcile with the observations that CB alone or with colchicine inhibits capping of lymphocytes¹¹ and that colchicine enhances capping in lymphocytes treated with con A (ref. 15). These discrepancies may be related to relative variations in the localisation, structure, quantity or association to membrane elements of microfilaments and microtubules in different cell types. This is supported by the absence of CB-induced redistribution in certain cell types in the study reported

Fig. 3 Cocapping of β_2 -m and actin in CB-treated Lu 106 cells. *a*, Distribution of β_2 -m detected by indirect FITC-staining; *b*, Distribution of actin detected by indirect TRITC-staining. The live cells were first stained by rabbit anti- β_2 -m, diluted 1:20 and an absorbed sheep anti-rabbit IgG, diluted 1:5, 30 min, 0 °C respectively. Subsequently, CB 10 μ g in 1 ml was added and the cells incubated 60 min and then acetone-fixed. Actin was demonstrated by staining with a human anti-actin serum diluted 1:20 and an absorbed sheep anti-human conjugate diluted 1:2.5.

here. Such differences could conceivably influence both the nature and the magnitude of the cellular response to the two compounds. Thus, it is important to determine when CB and colchicine, respectively, induce and antagonise membrane mobility and to characterise the cellular basis for this difference between different cell types.

This work was supported by the Swedish MRC. Dr Fagraeus supplied purified actin; and E. Bergdahl and K. Winberg gave skillful technical assistance.

X-ray diffraction studies of circular superhelical DNA at 300–10,000-Å resolution

G. W. Brady & D. B. Fein*

Bell Laboratories, Murray Hill, New Jersey 07974

H. Brumberger

Department of Chemistry, Syracuse University, Syracuse, New York 13210

X-ray diffraction studies on circular superhelical DNA from bacteriophage PM2 at a very low scattering angle show that it is possible to measure the superhelical scattering function of the molecule. The results suggest that in addition to the primary supercoil, a higher order of supercoiling of the DNA is present, an effect which can be interpreted with a simple analogue.

THE supercoiling of circular double helical DNA, first demonstrated by Vinograd, has been studied by various physical and

chemical techniques¹. If the superhelix turns are fairly uniformly distributed, the periodicity should give rise to maxima in the X-ray diffraction pattern, the position of which depends on the precise geometry of the superhelix. Depending on the correct value of the superhelix density (which has been in dispute for some time) and on the addition of unwinding agents such as intercalating molecules (for example, ethidium bromide), the diffraction maxima are expected in the range from several thousand Angstroms down. Accordingly, we have explored the low angle diffraction from dilute solutions of circular superhelical DNA from PM2 bacteriophage² from about 10,000 Å down to about 300 Å. Two significant maxima are observed. The first, due to the "native" superhelix, appears at angles corresponding to a Bragg spacing of 337 Å. The second is observed at 2,100 Å, increasing with the addition of ethidium bromide (EB), in a manner to be expected if the latter unwinds

*Present address: New York State Department of Health, Division of Laboratories and Research, Empire State Plaza, Albany, New York 12201 and Department of Physics, State University of New York at Albany, Albany, New York 12222.

Fig. 1 Schematic drawing of the Bonse-Hart design for low angle X-ray scattering.

the helix. These results suggest that in addition to the primary supercoil, a higher order of supercoiling of the DNA is also present, an effect which can be interpreted with a simple analogue. A more general conclusion is that with the methods described here it is possible to observe the helix in an environment approaching that of *in vivo* conditions.

The DNA used in these studies was prepared according to the methods of Espejo *et al.*² from the bacteriophage PM2, which was grown and purified using modifications of previously published methods³⁻⁵. We verified that the intact DNA was in the closed circular supercoiled conformation by sedimentation velocity studies in alkaline and neutral CsCl and by Agarose gel electrophoresis. Nicked samples were prepared as required with pancreatic DNase.

The DNA usually had an absorbance ratio at 260–280 nm of 1.95–2.0. When examined in alkaline and neutral CsCl in the Beckman Model E ultracentrifuge using a Vinograd band-forming cell, only one band was visible. The DNA was further concentrated, when required, by vacuum evaporation. By this method, the solution could be reduced to about 1/100 of the original volume. After concentration, it was again dialysed against buffer (0.1 M NaCl, 0.2 M Tris (pH 7.5), 1 mM disodium EDTA), frozen quickly in a dry ice-acetone mix, and stored at -20°C . The DNA concentration used in the experiments was 2 mg ml^{-1} , at 0.1 M salt concentration.

Two sets of X-ray measurements were made. Those for scattering angles greater than $300\text{ s } 2\theta$ were taken with a Kratky camera using $\text{CuK}\alpha$ radiation; those in the scattering range

from $12\text{--}300\text{ s}$ were made with a small-angle apparatus constructed after the principle first demonstrated by Bonse and Hart⁶. The Kratky camera and its operation are well known⁴ and we need not discuss further the technique of that set of measurements. The Bonse-Hart apparatus is more unusual. In this arrangement two grooved germanium single crystals, one placed before and one after the sample, serve, by multiple reflection, to produce a narrow incident beam (in our case 12 s wide at half maximum). By this technique, highly collimated incident beams are produced without the necessity of using complicated slit geometries (Fig. 1). Since the rocking angle of these almost perfect crystals is so small (9 arc s) the analyser crystal and counter is placed only a few centimetres from the sample, instead of several metres, which would be required with a conventional low-angle camera. A resolution of $10,000\text{ \AA}$ is attainable, and the diffracted intensity at very low angles is much greater than with the Kratky camera. Because the beam is defined by the fixed reflection geometry, there is no way of increasing the intensity at the high angle end of the pattern; for the system studied here the intensity was at background level above $300\text{ s } 2\theta$, thus limiting the range of the apparatus to angles less than $300\text{ s } 2\theta$.

The zero position of the apparatus was determined by stepping through the main beam in steps of 1 s , with the beam attenuated to within measurable intensity by means of suitably calibrated copper filters. After the zero was located, the filters were removed and the patterns were recorded. Readings were taken between 12 and $300\text{ s } 2\theta$ with $\text{CuK}\alpha$ radiation ($\lambda = 1.54\text{ \AA}$). The sample was contained in a cell with a 1-mm path length with windows made from cleaved mica sheets, and the intensity difference between the cell full and empty after corrections for absorption varied from 30% at the lower end of the angular range angles to 15% at the higher end.

Table 1 Distances corresponding to peak maxima

EB/nucleotide	d_{Bragg}
0 (nicked)	
0 (un-nicked)	2,100
1:20	3,355
1:10	5,250
1:3	3,035

Fig. 2 Diffracted intensity (log scale) plotted against diffraction angle (2θ) in arc s. Curves: 1, Un-nicked PM2 DNA; 2, as 1 with EB added in 1:20 EB/nucleotide ratio; 3, as 1 with 1:10 EB/nucleotide; 4, nicked PM2 DNA; 5, as 1 with 1:3 EB/nucleotide. Inset, plot of a portion of curve 1, with error bars.

The scattering curves, corrected for background, are shown in Figs 2 and 4. We consider first the curves of Fig. 2, which show the scattering at very small angles. The molar concentration ratios of EB nucleotide are listed in the legend. A distinct, well defined peak is evident in curve 1 for supercoiled DNA without added EB. As EB is added, this peak moves in to lower angle, indicating an increasing correlation distance associated with the peak. In curve 3 the second-order peak is also evident, since the primary peak position (corresponding to a distance of $5,250\text{ \AA}$) occurs at such a small angle that the secondary peak is within the detectable range of the instrument.

Curve 4 is for a nicked sample where the superhelix is completely unwound. The scattering curve is smooth; the peak has disappeared. It reappears again in curve 5, at which concentration of EB the completely unwound superhelix begins to coil up in the opposite sense¹². The values of the distances corresponding to the peak maxima are listed in Table 1.

Figure 3 shows the reciprocals of the Bragg distances calculated from the peak maxima as a function of EB concentration. The relationship between the two is reasonably linear, except for the point on the left which is too high. This is in agreement with Freifelder's⁸ observation that the stiffness of the superhelix increases with addition of EB. Thus, Figs 2 and 3 are consistent with and most directly explained by ascribing the source of the scattering to a periodicity of the superhelix itself.

The peaks and the way they vary cannot be ascribed to maxima of a scattering function characterising the size and

Fig. 3 EB/nucleotide ratio plotted against the reciprocal of the peak spacings; this latter is proportional to the rotation angle of the helix (see discussion in text). The 1:3 point is plotted as negative to show that the winding up is in the opposite sense.

shape of the DNA molecule as a whole. As examples, the scattering functions for loose spherical aggregates or elongated rod-like cylinders or ellipses are not consistent with the measurements. In the first case, a sphere radius derived from the position of the first maximum would result in a sphere volume so large that only a fraction (10^{-4}) of it could be filled by the superhelix volume. The length of the PM2 DNA molecule is 36,000 Å. For cylinders with radii of gyration consistent with the inner slopes of the curves, the peaks would have to appear at angles much further out on the scattering curve. Also, in this case, since the added EB causes the peak to move inward, consistent with an unwinding of the helix, its behaviour is opposite to that to be expected for the increase in asymmetry of an elongating rod-like structure, which would, of course, cause an outward shift of the peak. Finally, a random loop of these dimensions would not give peaks of any measurable intensity. This is evidenced by the nicked sample which does not show these effects at all. If we take the scattering curve of the nicked sample as resulting from a scattering function characteristic of the morphology (see also Fig. 4), the scattering function of which the peaks are a part appears to be superimposed on it. It is not possible at present, however, to isolate the scattering function of the helix from the total curve. A proper separation would require a better knowledge of the morphology of the

Fig. 4 Diffracted intensity measured at larger angles. Curves: 1, PM2 DNA with 1:53 EB/nucleotide; 2, PM2 DNA; 3, calf thymus DNA.

molecule, but even more important, an added difficulty is the nicking effect of the radiation on the helix, which makes quantitative intensities extremely hard to measure. The conformation of superhelical DNA is very sensitive to X rays⁹ and one of our major concerns was whether the material would last long enough in the superhelical form for the experiment to be done. After a 6-h experiment, ultracentrifugal analysis of the specimen indicated that 65% of the material was in the superhelical form whereas almost 100% was when the experiment began. This degradation was tolerable because while it changed the peak intensities relative to the background, it did not shift the peaks bodily and the spacings calculated from the maxima are unaffected. Because of the degradation, the intensities of the different curves of Fig. 2 are not directly comparable with each other and do not measure in any way the relative amount of helical material as a function of added EB. Also, because of the uncertainty in peak-to-background ratios, it was not felt appropriate to slit desmear the curves.

Table 2 Values of radius, helix repeat and contour length

<i>a</i> $d_{\text{obs}} = 337 \text{ \AA}$			
	<i>r</i>	<i>p</i>	<i>c</i>
	85	838	994
	90	608	830
	95	513	787
	100	460	779
	125	357	863
<i>b</i> $d_{\text{obs}} = 2,100 \text{ \AA}$			
	510	8,639	9,214
	550	4,124	5,380
	600	3,097	4,879
	700	2,442	5,030
	800	2,188	3,482

Before analysing these results further, we turn to the measurements with the Kratky in the range between 300 and 1,200 s 2θ, shown in Fig. 4. In these experiments the three systems examined were PM2 superhelical DNA with EB added in the ratio of EB/nucleotide = 0.19, corresponding to that concentration where the curve of Fig. 3 intercepts the ordinate (the unwound helix), PM2 superhelical DNA, and calf thymus DNA, which is not superhelical. It can be seen that whereas curves 1 and 3 show no indication of a maximum, curve 2 for the superhelix does. Its intensity is of the same order of magnitude as those of Fig. 2. We thus identify the peak as arising from the superhelical structure. The Bragg spacing corresponding to the peak maximum is ~337 Å. For helical structures randomly oriented, without long range order, the first maximum observed would be the first layer line¹⁰. The reciprocal space radius of this maximum is related to the helix repeat distance and to the helix radius. Since the first maximum of the first order Bessel function occurs at an argument of 1.84, we have from the relationship $2\pi rR = 1.84$, that R for the first maximum is equal to $1.84/2\pi r$, where r is the helix radius. The theory relates the first maximum to the helical parameters through the relationship

$$\left(\frac{1.23}{d_{\text{obs}}}\right)^2 = \left(\frac{1.84}{2\pi r}\right)^2 + \left(\frac{1}{p}\right)^2 \quad (1)$$

where p is the helix repeat. The factor 1.23 in the numerator on the left hand side is introduced to account for the difference in spacing measured in a single randomly oriented helix from that of a crystalline arrangement of helices¹¹. Similarly, for one turn of a helix the contour length c given by

$$c^2 = 4\pi^2 r^2 + p^2 \quad (2)$$

Our measurements give only d_{obs} and we cannot evaluate r and p separately. We can, however, determine values of p for various values of r and these are listed in Table 2, together with

the contour lengths calculated from equation (2). The minimum value of r from equation (1) is 80.2 Å. The values of p in Table 2 lie in the range between 800 and 300 Å, depending on the radius. Comparative values are 600 Å, deduced from hydrodynamic measurements by Gray *et al.*^{12,13}, and 300 Å, calculated by Wang¹⁴. The values of the radii, consistent with our measurements, are considerably greater than the diameter of the double helix, indicating that the hydrated superhelix is considerably

increasing distance upward from the bottom of the model. No correspondence with the elastic and mechanical moduli of the DNA is claimed for the analogue, nor can it depict visually the intervening space between the two double helices; but it shows that if the superhelix conformation is indeed primarily the result of a torsionally strained primary helix, then it will of necessity be accompanied by a second order helix, and this is what our measurements imply.

Fig. 5 Photograph of analogue model for the superhelix. The first-order superhelix is represented by the two intertwined chains which run from top to bottom of the model. The second-order superhelix is clearly seen as an additional superimposed helix (see text).

expanded, and should not be regarded as being equivalent to two DNA helical strands tightly wound together. Superhelical formation is the result of residual strain in the double helix, and does not result from attraction between the groups on its exterior; in fact, we would expect a net repulsion between peripheral PO_4^- groups. Thus we suspect that solvent interactions would make an important contribution to the final conformation.

These results place the interpretation of the curves of Fig. 2 on a firmer basis. We believe that they result from scattering from a higher order superhelix which is imposed on the primary superhelix by the mechanical properties of the double helical DNA molecule, whose strain is not completely relieved by the formation of the superhelix. The residual strain is distributed uniformly over the superhelix and leads it to adopt, in turn, a helical conformation of the opposite sense to the superhelix. To illustrate this with a model poses the difficulty of how to approximate the conformation of a strand of DNA when, in addition to being distorted by the residual strain, it is affected by interaction with the solvent medium. The resulting complex local distortions thus produced must be correlated over distances equivalent to the superhelix dimensions, and in general molecular models are not flexible enough to act as useful guides in determining the final conformation of such a complicated molecule when in the liquid state. As a means of circumventing this difficulty and to illustrate how a flexible helical macromolecule under strain is constrained to adopt the configuration we have described, Fig. 5 shows an analogue model. The analogue is made of rubber tubing which is twisted a few times, after which the two ends are joined to form a closed loop. The closed loop is the analogue of the double helical molecule and the imposed twist is the equivalent of the residual strain of the double helical configuration of the DNA. Because of the flexibility of the tubing, the strain is propagated uniformly along its length. When the tubing is released after closing, the loop supercoils. In the photograph the supercoil is identified as the series of small loops which extend from top to bottom of the model. Its period gives rise to the diffraction maxima observed at the higher angles. Its sense is opposite to that imposed on the tubing. Clearly evident in the photograph is another higher order helix of sense opposite to that of the superhelix. The analogue is of course distorted by gravitation, the effect of which can be clearly seen in the photograph, manifested by an increased pitch and decreased radius with

No theoretical analysis of the strain phenomenon exists, so there is no way to estimate how the strain is partitioned between the primary and second order helix, and thus be able to calculate the ratio of the number of turns between the two. We content ourselves with again listing in Table 2b the values of p , c and r corresponding to $d_{\text{obs}} = 2,100$ Å. The minimum radius is ~ 500 Å. For intermediate ratios of pitch to radius, we see from the contour length that the number of superhelix turns in one second order turn is about 6. Furthermore, since the superhelix length is 16,000 Å, there are three second-order turns per molecule.

Because of the nicking effect of the radiation and the low intensities involved, it is not possible to construct a complete composite curve from the two sets of intensity data. The overlap region of the scattering curves is differently affected by the different optical characteristics of the two diffractometers, and as we have noted, it is not possible, because of the nicking, to correct for this. Future work will be directed towards obtaining higher intensities, either by the use of a rotating anode tube, or by incorporation into the DNA of strongly scattering atoms. It will then be possible to extend the angular range of the Bonse-Hart to beyond 1,200 s. The nicking effect will be circumvented by using a position sensitive detector. It will then be possible to apply Fourier transform techniques to the data.

We thank R. Langridge and S. Lapedes for samples of nicked and un-nicked PM2 superhelical DNA and calf thymus DNA, and for stimulating discussions. We also thank D. Jones for help in preparing and standardising some of the samples in which EB was incorporated.

letters to nature

Phase transition from baryon to quark matter

THE equation of state of matter compressed to supernuclear densities is of considerable interest in astrophysics. For example, pulsars are stars compressed to densities greater than the density of atomic nuclei and are thought to be composed primarily of neutrons, based on detailed calculations of the equation of state of baryonic matter assuming that interaction potentials for the baryons (nucleons and hyperons) are derived from low energy nuclear physics¹. There is, however, considerable evidence from high energy physics that baryons have structure, and it is currently believed that this structure is due to the fact that all hadrons consist of quarks bound by vector gluons². The fact that free, isolated quarks have not been observed has led to the speculation that quarks may be permanently bound inside hadrons³. Since the quarks inside the nucleon behave as free particles², the forces confining the quarks apparently become strong only when the distance between quarks exceeds the radius of a nucleon, $\sim 10^{-13}$ cm. When the density of matter is increased beyond the point that the mean distance between quarks in different baryons is $\ll 10^{-13}$ cm the description of matter as interacting baryons becomes invalid, and instead, a description of matter composed of quarks becomes relevant. At sufficiently high densities matter will behave like a relativistic gas of free quarks⁴ with $P \simeq \rho/3$, where P is the pressure and ρ is the energy density of matter. The density at which the baryon to quark transition occurs is of crucial importance to the structure of pulsars. General relativity implies that for a given equation of state there is a maximum energy density for stable stars¹. It is therefore of considerable interest to know whether the energy density of baryon matter at the baryon-quark phase transition is less than this maximum value. Indeed, it has recently been suggested⁵ that the existence of quark matter inside pulsars would allow larger masses for pulsars than was previously thought possible. We will show, however, that there are reasons to doubt this.

To determine the density for the baryon-quark matter transition one needs a theory of quark confinement. Although a detailed theory of confinement is not yet available, a phenomenological theory has recently been proposed⁶ in which the confinement is caused by a universal pressure B on the surface of any region containing quarks. Such a description is consistent with relativity and accounts for many observed

the density at which baryon matter changes to quark matter at zero temperature. At a fixed pressure P and zero temperature the appropriate phase of matter is the one which has the lowest Gibbs energy $\mu = (P + \rho)/n$, where n is the conserved baryon number density. Equating the Gibbs energy for quark matter and for baryon matter at the same pressure then determines the transition point.

Assuming that quark confinement is due to a phenomenological pressure B in the domain occupied by quarks, and that quarks moving inside this domain interact weakly by gluon exchange⁶, it is straightforward to calculate the thermodynamic functions of quark matter. The ground state of quark matter is a Fermi gas with all 'colour' states occupied for each level up to the Fermi level. When the Fermi energy of the quarks is large compared with the quark masses the energy density at zero temperature on dimensional grounds has the form

$$\rho = An^{4/3} + B \quad (1)$$

where A is a constant proportional to $\hbar c$, and n is conserved even when baryons no longer exist. The constant A depends on the dimensionless quark-gluon coupling constant g , and to second order in g we obtain

$$A = \frac{9}{4} \left(\frac{3\pi^2}{\kappa} \right)^{1/3} \left(1 + \frac{8g^2}{3\pi} \right) \hbar c \quad (2)$$

where κ is the number of quark 'flavours' contributing to the energy density. From equation (1) we obtain the pressure P of quark matter

$$P = \frac{A}{3} n^{4/3} - B \quad (3)$$

and correspondingly the Gibbs energy per unit baryon number, μ , as a function of P for zero temperature

$$\mu = 4 \left(\frac{A}{3} \right)^{3/4} (P + B)^{1/4} \quad (4)$$

Table 1 Baryon energy density (ρ_c) in units of 10^{15} g cm⁻³ where baryons begin to disappear

	$g^2 = 0.55$ $B = 9.5 \times 10^{34}$ erg cm ⁻³	$g^2 = 0.75$ $B = 5.1 \times 10^{34}$ erg cm ⁻³
Pandharipande-Smith (3)	2.7	4.0
Bethe-Johnson (I)	6.5	9.0
Bethe-Johnson (VH)	13	18

The values of g^2 and B are two sets of MIT 'bag' parameters which agree with observed hadron properties⁷, with $\kappa = 3$. Pandharipande-Smith and Bethe-Johnson refer to two recent models of baryon matter^{8,9}.

properties of hadrons when the effect of gluon exchanges between quarks is included⁷. We obtain here the equation of state of quark matter in this theory including gluon effects to first order in the gluon-quark coupling constant g . We then apply Gibbs' criterion for a phase transition to calculate

To find the baryon-quark phase transition we must equate μ as calculated from equation (4) with calculations of μ for baryon matter. Typical results of such a comparison are shown in Table 1. The results are given for the best currently available estimates⁷ of g and B and for two recent calculations^{8,9} of the properties of cold baryon matter. It can be seen that the transition takes place at baryon energy densities which are 10-60 times the baryon energy density in normal nuclei. Both the quark number density and energy density at the transition are higher than the corresponding baryonic densities indicating that this is a first-order transition. Since the baryon matter calculations were based on nucleon-nucleon potentials derived from low energy nuclear physics their validity at the transition density is open to question. Nevertheless, the calculations should be reliable in their indication that the transition takes

place at densities considerably in excess of those in normal nuclei. Furthermore, since the baryon-quark phase transition occurs at an energy density which is higher than the maximum density calculated for neutron stars^{9,10} speculations⁵ that the existence of quark matter inside pulsars would allow larger masses for these objects than had been calculated using baryon equations of state are unfounded.

Applying the equation of state for quark matter, equations (1-3), we now evaluate the maximum density P_m for stable quark stars in general relativity. This density is given approximately by the condition that $\gamma = \gamma_c$, where $\gamma = d \ln P / d \ln n$ is the adiabatic index for quark matter ($= \frac{1}{3}(1 + \rho/P)$ from (3)) and γ_c is a universal function of P/ρ (ref. 11). From this condition we find $\rho_m = 8.3B$ which is lower than the energy density, the baryon-quark phase transition for all the cases investigated here (see Table 1). Thus, a consistent application of the phenomenological MIT model for quark confinement to second order in g leads to the conclusion that stable quark stars at zero temperature do not exist.

Supported in part by a grant from the NSF.

Note added in proof: after submitting our letter we received a preprint by G. Baym and S. Chin in which similar results for the baryon-quark phase transition are obtained.

High electric fields from industrial stack plumes

THE use of electrostatic precipitators on an industrial stack to remove particulate matter and aerosol particles is now quite common. The plume emanating from such an installation is likely to be highly electrically charged, and consequently associated electrical effects should be observable downwind of the stack.

Measurements were carried out from July 6 to July 10, 1976 of the vertical component of the electric field downwind of a 110-m chimney stack of a cement works at Eastgate, Co. Durham, using a series of conventional field mills¹. Eastgate, ~33 km W of Durham City, is sited in a broad valley, 235 m above m.s.l., running E-W into the Pennine chain. The weather conditions were slightly unstable and cloudless with an easterly wind of between 3 and 4 m s⁻¹ measured at 2 m above ground. Averages of readings taken over 10-min periods at 15-s intervals yield electric field values in the region of +4,000 V m⁻¹ at sites within 500 m of the stack. Peak values up to +10,000 V m⁻¹ were recorded within the same distance from the stack. The direction of the electric field corresponds to a negatively charged plume caused by an applied -60 kV to the corona wires of the electrostatic precipitators. The high electric field values can be compared with a typical value of the normal fair weather electric field upwind of the stack of ~-200 V m⁻¹.

Large perturbations in the normal electric field were observable for distances up to 8 km downwind of the chimney stack. The decay in the electric field, E_p , at a position P was found to

agree with the fundamental line charge equation², modified by an empirical dissipation factor $\exp(-x/d)$ as follows

$$E_p = \frac{\lambda}{2\pi\epsilon_0 h} \left[1 + \frac{x}{(x^2 + h^2)^{1/2}} \right] \exp(-x/d) \quad (1)$$

where λ is the electric charge per unit length, h is the height of the plume, x is the distance of the position P downwind of the stack, ϵ_0 is the permittivity of free space, and d is the distance at which the electric field is reduced to $1/e$ of its initial value. Experimental results indicate that d possessed values of between 1 and 2 km. The effect of turbulent diffusion in the plume was estimated from the plume observations to be sufficiently small to validate the line charge approximation up to at least 2 km downwind of the stack.

In view of the high values of the electric field, a series of experiments was performed to establish the occurrence of point discharge. Measurements of point discharge current from an insulated elevated point, 9.25 m above ground level, were made at 15-s intervals by means of a Keithley electrometer, model 640, 700 m downwind of the stack. Simultaneous measurements were made of the electric field at a distance 10 m upwind of the point. It was found that an electric field of 2.2 kV m⁻¹ was necessary to initiate the point discharge. A maximum value of point discharge current of 3 μ A was observed over a 20-min period. It was also found that the point discharge current, i , and the electric field, E , followed the theoretical relationship³

$$i = k(E - E_0) \quad (2)$$

closely, where k is a constant, E is the value of electric field and E_0 is the onset value of electric field for the occurrence of point discharge.

In studying the dispersal of plumes by atmospheric turbulence, the electrical methods described here may provide a useful supplement to conventional concentration and dosage measurements^{4,5}. The flow of negative charge away from the stack in the form of the charged plume leads to an equal positive current flow down the stack to Earth. Taking into consideration the numerous chimney stacks in operation, it is reasonable to assert that this hitherto unknown charge separation process could significantly modify estimates of the Earth's electrical current 'balance sheet'⁶.

The presence of large electric fields in the vicinity of certain chimney stacks must result in significant point discharge currents occurring from sufficiently high metallic objects. If the objects concerned are poorly earthed they could acquire large electric potentials, which may well lead to electric spark production. This would not be of any practical consequence in most cases. If, however, the atmosphere downwind of the stack contained inflammable material, caused for example by an industrial leak, the occurrence of sparks could result in the ignition or detonation of the material.

The preliminary work described here will be elaborated in more detail in a subsequent publication.

Heat-resistant Fe–Cr alloy with polycarbosilane as binder

WITH the advances in recent years in high temperature gas-cooled reactors, jet engines and rockets, the constraints on heat-resistant materials are becoming more and more stringent; they must display high temperature strength, thermal shock resistance, high temperature corrosion resistance and toughness. Conventional heat-resistant materials can no longer meet these conditions¹. We report here the development of a new heat-resistant Fe–Cr alloy which has the required properties, based on the method for the conversion of an organic silicon polymer to an inorganic compound by heating which we have described previously^{2–3}.

Polycarbosilane (PC) is prepared as follows: suitable quantities of metallic sodium and xylene are mixed, and then heated to ~110 °C in a stream of inert gas. Dimethyldichlorosilane is then added. The chlorine in the dimethyldichlorosilane reacts with sodium on stirring, producing sodium chloride. By this reaction dimethyldichlorosilane turns into polysilane

which precipitates in the reaction vessel. The substance is recovered by filtration, washed and dried.

The purified polysilane is then put in an autoclave, and heated at 460 °C for 14 h with continuous stirring. The polysilane is thus converted to PC

with an average molecular weight of ~300–800. This is then heated to between 200 and 260 °C *in vacuo*, to remove the light molecular weight fraction by evaporation, and one is left with PC of average molecular weight ~1,000–2,000.

A mixture of powdered Fe–Cr alloy containing 13 per cent by weight of Cr (average grain size 3 μm) and PC of average molecular weight ~1,000 are weighed out in a ratio of 9:1. *n*-Hexane is added, the three are well mixed by kneading and the mixture is dried in air. At this stage, the particles of Fe–Cr alloy are uniformly covered with PC. It is hot pressed to obtain the moulding, using a carbon jig, at a pressure of 19.6 MPa in an atmosphere of Ar, with heating by high frequency induction, capable of giving 300 °C h⁻¹ and the moulding is kept at a maximum temperature of 1,100 °C for 30 min. The pressure is then released, the high frequency power source is switched off, and the moulding is left to cool naturally.

Powder X-ray diffraction using an Fe target with a Mn filter and transmission electron microscopic observation indicate the formation of spherical or ellipsoidal particle of Cr₇C₃ and CrSi₂ with a diameter of 1,500–2,500 Å. When polycarbosilane alone is heated at 1,000 °C in an inert gas

Fig. 1 The gain in weight against the heating time in air at 1,000 °C for the Fe–Cr alloy (x) and the Fe–Cr 10% by weight PC alloy (o); Δ, Ni–22Cr reference.

atmosphere, it decomposes, releasing CH₄ and H₂. The result is a skeleton of SiC, which is amorphous. If the Fe–Cr particles coated uniformly with PC are cold pressed and then heated at 1,100 °C, a reaction occurs between the Fe and Cr in the matrix and the amorphous SiC dispersed uniformly through the alloy, resulting in the formation of the silicide and carbide. A uniform distribution of silicide and carbide in the alloy is not obtained by introducing commercial α- or β-SiC into the powdered alloy and hot pressing.

Oxidation tests were made on the moulding obtained above, on a moulding made without PC and on the well know heat-resistant Ni–22Cr alloy as a reference, by heating in an electric furnace at 1,000 °C for 50 h. Figure 1 shows the weight gain from oxidation against the heating time for the Fe–Cr alloys at 1,000 °C in air. The weight increases in a parabolic curve in the Fe–Cr alloy without PC, but hardly increases at all in the moulding made with PC.

The surfaces of the mouldings after the tests were examined (Fig. 2a). Spalling of the oxidation film was found in the moulding without PC, but in the moulding with PC,

Fig. 2 a, Oxidation film of the alloy with (right) and without (left) PC after exposure to air for 50 h at 1,000 °C. b, Scanning electron microscopic observation of grain size in the two alloys (right with PC, left without).

only a slight film was observed which was firmly attached to the surface. This high resistance to oxidation may result from the stability of Cr_7C_3 and CrSi_2 against oxidation.

A value of 345 for the Vickers microhardness was obtained for the PC-coated alloy at room temperature—it is 100 in the PC-less alloy. Abrasion tests were made on the Fe–Cr alloys with Okoshi's testing apparatus. A disk of thickness 3 mm and diameter 30 mm was placed on the square $40 \times 40 \times 10$ -mm specimen, and a load of 7 kg was placed on the disk. The disk was rotated at 67 rad s^{-1} at room temperature. The value obtained for the abrasion resistance was $1.48 \times 10^{-6} \text{ mm}^2 \text{ kg}^{-1}$ in the Fe–Cr alloy with PC, and $7.10 \times 10^{-6} \text{ mm}^2 \text{ kg}^{-1}$ in the same alloy without PC.

The grain size of the mouldings heated at $1,000^\circ\text{C}$ for 5 h was examined with a scanning electron microscope after etching the surface with aqua-regia dissolved in glycerine. As seen in Fig. 2b, the grain size is $25 \mu\text{m}$ in the Fe–Cr alloy without PC, but in the alloy with 10% by weight of PC it is $9 \mu\text{m}$.

The large Vickers microhardness and the excellent abrasion resistance of the Fe–Cr alloy with PC can possibly be attributed to the existence of small particle Cr_7C_3 and CrSi_2 and the small grain size. This alloy may find many applications where heat resistance plus abrasion and oxidation resistance is required.

SiC sintered bodies with three-dimensional polycarbosilane as binder

As is well known, silicon carbide is a practical heat-resisting material, because it has high strength and excellent oxidation, corrosion and thermal shock resistance. It is, however, difficult to obtain it as a sintered body because of its poor sintering characteristics. The usual method¹ for obtaining SiC with high flexural strength are to add a sintering promoter to fine SiC powder followed by hot pressing. The process is complicated and not suitable for obtaining large products. We here report the synthesis of high purity SiC mouldings with high mechanical strength by low temperature ($1,000$ – $1,400^\circ\text{C}$) sintering of SiC powders bond with three-dimensional polycarbosilanes. The method is based on the conversion of an organosilicon polymer to the inorganic compound by heat treatment^{2–5}.

The SiC powders used are 99.99% pure α -SiC, with an average particle size of $3 \mu\text{m}$. To these are added 10% by weight of polycarbosilane (PC)^{6,7} with an average molecular weight of 800 dissolved in a suitable quantity of *n*-hexane, which is then removed by evaporation. Particles $10 \times 30 \times 4 \text{ mm}$ in size were obtained by pressing at 196 MPa at room temperature. Their temperature was raised at 100°C h^{-1} to 700 – $1,400^\circ\text{C}$ in a flow of 200 ml min^{-1} of N_2 , and kept at the desired temperatures for 1 h. Sintered SiC particles were produced; there were no shrinkage or expansion.

The flexural strength of the SiC at room temperature was measured in three-point bending test with an Instron

bending tester under ASTM testing conditions. The $10 \times 30 \times 4$ -mm specimen was tested at strain rate $8.3 \times 10^{-3} \text{ s}^{-1}$ with the span of 20 mm. Figure 1 shows the bending strength against the temperature at which sintering occurred. The bending strength increases with temperature up to $1,100^\circ\text{C}$, beyond which it keeps constant at 61.7 MN m^{-2} .

To increase the strength still further, 'PC impregnation' was carried out. SiC particles obtained as above were heated together with PC powder in an autoclave under a vacuum at 100°C for 30 min, and then heated at 350°C for 1 h at a pressure of 9.8 MPa (of Ar). The particles were

Table 1 Characteristics of SiC with 10% by weight of polycarbosilane and also KT-SiC

	SiC with PC	KT SiC ¹
Production temperature ($^\circ\text{C}$)	1,400	2,300 (hot press)
Impurity	$\sim 0\%$	Excess silicon or carbon
Apparent density (%)	70–80	100
Bending strength (MN m^{-2})	250	~ 168
Oxidation/acid resistance	Very high	Very high
Formability and dimensional precision	Excellent	Poor

then heated up to 700 – $1,400^\circ\text{C}$ at 100°C h^{-1} under a flow of N_2 . They were kept at these temperatures for 1 h.

The effect of PC impregnation is indicated in Fig. 2. It is seen that the apparent density and the bending strength both increase linearly with repetition of the process. The apparent density of the SiC particles after five cycles is 83.0% and the corresponding bending strength is 250 MN m^{-2} . A feature of the SiC particles thus fabricated is their exceptionally high bending strength for a low density. In Table 1, one sees that the bending strength of our SiC is 250 MN m^{-2} , while it is $\sim 168 \text{ MN m}^{-2}$ for KT-SiC.

The amount of PC added to the SiC was varied—and the addition of 10% by weight was found to be the most suitable. For a sintering temperature of $1,000^\circ\text{C}$ for example,

Fig. 1 Bending strength against sintering temperature.

Fig. 2 Bending strength and apparent density against repetition of the PC impregnation cycle; sintering temperature 1,000 °C under flow of N₂, without heating in the air.

the bending strengths were 24.5 MN m⁻² for 5% by weight, 61.7 MN m⁻² for 10% by weight and 24.5 MN m⁻² for 15% by weight.

That SiC with PC has high mechanical strength, is interesting for the theory of sintering. In another experiment, SiC powder (particle size ~3 μm) and very fine SiC particles (~100 Å) (refs 2, 3) obtained by the decomposition of PC were sintered by heating. No contraction or expansion was observed. The diffusion coefficient of C in SiC is small— 3×10^{-13} cm² s⁻¹, at 1,800 °C, (S. Prochazka, unpublished)—so the mechanism cannot be simply explained by the normal idea of diffusional sintering. There is no dimensional change, and therefore one possibility may be condensation by PC evaporation.

When SiC particles were kept at 1,400 °C in air for 2, 5 and 10 h, the gains in weight from oxidation were 4.41, 5.70 and 7.01 mg cm⁻², respectively. Beyond 10 h, there is no increase. Bending strength after oxidation was measured. For sintering at 1,000 °C under N₂ flow, for example, it was 56.8 MN m⁻² in Fig. 1, but increased to 147 MN m⁻² after being kept in air at 1,400 °C for 10 h—the SiC is not only resistant to oxidation, but its bending strength increases. This phenomenon is being studied at present, but preliminary powder X-ray diffraction indicates that a very small amount of Si₃N₄O was produced on oxidation and this acts as a binder, thereby raising the bending strength.

The SiC was immersed in boiling solutions of 20% HCl and 50% HNO₃ for 100 h. It would have lost 0.05 mm of surface material in a year, and is therefore extremely stable in boiling acid solutions.

For SiC in current use, a different substance is used as the binder, so the SiC content in them cannot be >98%. For SiC with PC, however, there is hardly any chance for other elements than Si and C to be present. The product is thus of high purity; chemical analysis showed the SiC content to be almost 100%.

The SiC thus developed are easily produced industrially and may find a use in many fields, including the construction of chemical plants.

Solar activity geomagnetic field and terrestrial weather

It has long been known that geomagnetic disturbances tend to recur after ~ 27 d (refs 1–4). More recently, this effect has been associated with the rotation of the interplanetary magnetic field^{5–8}, and some evidence for a relation between the interplanetary magnetic field and terrestrial weather has also been found^{9,10}. The interplanetary magnetic field is usually characterised by either two or four sectors, and this pattern rotates with a fairly well defined period of 27.1 ± 0.1 d (ref. 7). Such a periodicity leads naturally to the use of spectral analysis as an independent test of the reported association between the interplanetary magnetic field structure and terrestrial weather. We have obtained data on the geomagnetic activity index A_p for the 1964–70 from the National Oceanic and Atmospheric Administration and the vorticity area index used by Wilcox and his colleagues in their analysis⁹ for the same interval. We wish to form spectra of both time series and examine the spectra for common features which may be associated with solar related phenomena. Specifically we look for peaks in the power spectra of both time series with periods near 27.1 d.

Both the A_p and vorticity area index exhibit annual variations and long term trends. The annual variations and long term trends were removed from both data sets and the resultant series normalised so that the average of each index is zero. We have calculated least-squares estimates of the Fourier components of both normalised data sets for 1,921 periods (P) between 4 and 64 d. The estimates of the Fourier components a and b were calculated by varying a and b to minimise

$$V_3 = \sum_{n=1}^N \left[x_n - a \cos\left(\frac{2\pi}{P} n\right) - b \sin\left(\frac{2\pi}{P} n\right) \right]^2 \quad (1)$$

where the x_n are the normalised data points and N is the total number of data points.

After we had computed the Fourier components for both indices, we needed some way to compare the spectra and assess the significance of the results. We also needed some check that any periodicity found was indeed solar related, since both indices are of terrestrial origin. We have compared the spectra in three different ways.

One common method of assessing the significance of a least-squares fit¹¹ is to compare the residual deviation V_3 to the deviation of the data before fitting

$$V_1 = \sum_{n=1}^N x_n^2 \quad (2)$$

by forming the statistic

$$F_{2,N-3} = \frac{N-3}{2} \frac{V_1 - V_3}{V_3} \quad (3)$$

We have calculated the F statistic for each spectrum but, to compare the spectra, we tabulated the lesser of the two F statistics as a function of period. The largest peak in the resultant 'comparison spectrum' occurred at a period of 27.49 d. We may use the F statistic to determine the probabilities that the calculated reductions in variance are due to chance. Following Abramowitz and Stegun¹², we find the probability that the fit at 27.49 d arisen by chance for the A_p spectrum is $\sim 1.2 \times 10^{-4}$ and for the vorticity spectrum is $\sim 1.2 \times 10^{-6}$.

The F statistic calculated from the data is distributed only approximately as $F_{2,N-3}$, so that using such low probability estimates is probably not justified. We therefore arbitrarily use the lowest probability tabulated by Abramowitz and Stegun¹² for the F distribution which is 10^{-3} . If the A_p and vorticity indices are independent, then the probability that both indices would exhibit fits of this significance for a given period is $\sim 10^{-6}$. To obtain a significance estimate, it is essential to allow for the fact that the period was not chosen *a priori*, but inferred from the data. A generous estimate of the range of periods to be investigated is the range of observed synodic rotation periods of the photosphere of the Sun, namely 26.87–28.98 d (ref. 14). Accordingly, least-squares fits were calculated for 22 periods in this range. The probability of obtaining at least one of 22 probability estimates as small as 10^{-6} is $\lesssim 2.2 \times 10^{-5}$ if all of the periods are statistically independent. The length of our sample implies an intrinsic line width of 2.46×10^{-3} d⁻¹ and the spacing between the 22 periods is 0.77×10^{-3} d⁻¹. This indicates that not all of the 22 periods can be considered independent. We therefore think that calculating the probability estimates as if the 22 periods were independent produces a conservative probability estimate. Since for reasons stated above, we apply an arbitrary cutoff at 10^{-3} to estimates based on the F statistic, we have also calculated an empirical probability estimate. The F statistics for all the 1,921 periods analysed were ranked, and the probability of each fit estimated by the rank of the fit divided by the number of periods for which each spectrum was estimated. To compare the spectra, the larger of these two probabilities was tabulated as a function of period. There were two periods (19.88 and 44.52 d) with (chance) probabilities as low as or lower than the probability for the 27.49-d period. All three probabilities were, however, close together (26/1921, 27/1921, and 27/1921) and the next most significant peak had a probability estimate approximately twice as large (52/1921). If we combine the two empirical probability estimates in the same manner as the estimates from the F test, we find that the peak at 27.49 d has the smallest probability estimate ($\sim 3 \times 10^{-5}$) of any of the periods analysed by more than a factor of two. When we compensate for the fact that the period is chosen *a posteriori*, the empirical probability estimate that the observed result was produced by chance becomes $\lesssim 7 \times 10^{-4}$. Since both the A_p and vorticity indices are terrestrial, the assumption that the two indices are independent may not be justified. We therefore

explored a third procedure, based on the assumption that the relation between the A_p index and the interplanetary magnetic field structure is sufficiently well established that we may use the A_p spectrum to establish a rotation period. This assumption implicitly involves the supposition that there are no periodic meteorological phenomena with periods close to the solar rotation period that affect the geomagnetic activity index. We may then accept the probability estimates for the 27.49-d period in the vorticity spectrum. These estimates are $\lesssim 10^{-3}$ and $\sim 1.4 \times 10^{-3}$ for the F test and empirical probability estimates respectively.

Even if we accept the reality of the peaks in the spectra at 27.49 d, it is desirable to have some check that these peaks are associated with solar rotation. One fairly simple check is based on the fact that the Earth's orbit is slightly eccentric, and this eccentricity causes a variation of the apparent rotation period of the Sun through the calendar year¹⁵. The eccentricity of the Earth's orbit may easily be taken into account (to first order in the eccentricity) by slightly modifying the argument of the sine and cosine functions in equation (1). We have generated 'eccentricity corrected' spectra for both data sets and evaluated the results in the same manner as the uncorrected spectra. The F statistics for both A_p and vorticity indices were higher in the 'corrected spectra', but the probability estimates from the F test were not changed since we adopted an arbitrary cutoff at 10^{-3} . For the empirical probability estimates, the results were approximately the same as those for the uncorrected spectra; however, other peaks were degraded, with the result that the peak at 27.49 d had the lowest rather than the second lowest probability estimate. If we accept the period determined from A_p spectrum as a solar rotation period, the empirical estimate of the probability that the calculated fit in the vorticity index 'corrected' spectrum was produced by chance is $\lesssim 1.3 \times 10^{-3}$.

We have attempted to assess the significance of the observed peaks under various assumptions. The results vary from $> 99.99\%$ to $\sim 98\%$. We feel that the former estimate is unrealistically high; however, the decision to accept any of the estimates is subjective. Our own feeling is that the most reasonable procedure is to accept the period derived from the A_p spectrum as solar related. We therefore feel that the results of our analysis are significant at the 98% level. We do not feel that our analysis establishes a connection between the vorticity area index and solar activity, but we do feel that it provides supporting evidence for such a connection.

We would like to thank Drs John Wilcox and Phillip Scherrer for providing the vorticity area data in machine readable form, and Dr Oscar Buneman for making available a copy of his fast Fourier transform program. This work was supported by NASA and the Office of Naval Research.

Volatilisation from solid particles of the regolith

WE have previously¹ dwelt on the possible volatilisation of some elements from continuous melts of lunar surface material as a result of which it becomes depleted in elements such as Na, K and Rb, and so on. The mechanism of volatilisation proper was not confined to the liquid phase, and so they can also volatilise from the solid phase. Moreover, if solidification is not accompanied by crystallisation, the temperature dependence of the volatilisation time constant τ_v found in ref. 1 should remain unchanged.

Table 1 Calculated values τ_v for volatilisation of Na from lunar material (terrestrial time)

Particle size (cm)	Surface temperature (K)			
	1,500	900	500	300
1	15 h	5 d	25 d	300 yr
10^{-3}	0.15 h	1.2 h	0.25 h	3 yr

Table 1 gives the calculated values τ_v for the volatilisation of Na (see ref. 1) from the liquid and solid lunar material. For regolith particles the value τ_v is negligible compared with the geological time scale since $\tau_v \propto d$.

In ref. 1 the assumption that the lunar surface material was liquid was used only so that the complicated process of the transport of volatile elements to the surface could be ignored. In the solid phase, however, it is just their transport to the surface that may be the weak point of the calculation of the depletion process.

In this case the transport mechanism is mainly diffusive and, hence, a simple estimate of the diffusion time constant τ_d can be carried out

$$\tau_d = \frac{d^2}{D}; \quad D \sim \exp(-E_a/RT_s)$$

where D is the diffusion coefficient and E_a is the diffusion activation energy.

Since the dependence of τ_v on d is linear¹

$$\tau_v = \tau_{0v}d \quad (1)$$

where

$$\tau_{0v} \sim \exp[-(L-A)/RT_s]$$

and $(L-A)$ is the effective heat of evaporation^{1,2}, the depletion process will be limited by volatilisation ($\tau_v \gg \tau_d$) in the region of the smallest particles and by diffusion ($\tau_d \gg \tau_v$) in the region of large particles. The boundary between these regions $d = d_1$ can be determined from the condition $\tau_v = \tau_d$; then

$$d_1 = D\tau_{0v} \sim \exp[-(E_a - (L-A))/RT_s] \quad (1a)$$

The quantities E_a and $(L-A)$ have a similar physical meaning, and the difference between them $E_s = E_a - L + A$ should be close to the heat of adsorption, that is, it should be of the order of kcalorie mol⁻¹ (ref. 2).

Using equation (1), one can show that, at all temperatures of interest ($250 \text{ K} \lesssim T_0 \lesssim 1,500 \text{ K}$), the value of d_1 lies within the region of regolith particle sizes, $\sim 10^{-4}$ – 10^{-1} cm, and because $E_s > 0$ it increases with decreasing temperature.

In general, putting $\tau_0 = \max(\tau_v, \tau_d)$, one may assume that the rate of depletion of volatile elements from lunar material is determined by the time constant of the process 'weak point' τ_0 ($\tau_0 \lesssim 10^4$ yr for $d \lesssim 10^{-1}$ cm and $250 \text{ K} \lesssim T_s \lesssim 400 \text{ K}$). This interval corresponds approximately to the temperature

variations, T_s , of the upper layers of the regolith during the lunar day.

Since volatilisation and diffusion occur only in the day, and are almost totally switched off at night, the effective value τ_0 for the lunar day does not increase more than twice.

Next, it should be kept in mind that under meteoroid bombardment, and some other factors, the regolith particles, at least those from the uppermost layer ($h \simeq 10^{-1}$ cm), plunge into the lower ($h \lesssim 1$ cm) layers and then rise to the surface, intermixing at the rate $U_p \simeq 1 \text{ cm}/10^6 \text{ yr}$ (ref. 3). On the other hand, it is known^{3,4} that the rate of regolith formation is $U_f \simeq 10^{-1} \text{ cm}/10^6 \text{ yr}$.

Thus, for the regolith upper layer ($h \simeq 10^{-1}$ cm) one has the following inequality

$$\tau_0 \ll \tau_p \ll \tau_f \quad (2)$$

where $\tau_0 \lesssim 10^4$ yr, $\tau_p = h/U_p \simeq 10^6$ yr, and $\tau_f = h/U_f \simeq 10^6$ yr, τ_p and τ_f being the time constants of the corresponding processes.

The relationship between τ_p and τ_f shows that each regolith particle of a given layer was on the surface > 10 times whereas the first inequality in equation (2) implies that even a single sojourn of a particle on the surface is sufficient for the particle material to be significantly depleted in volatile elements.

Earlier we have shown theoretically and experimentally^{1,5} that the process of volatilisation from the liquid phase as a result of meteoroid impacts is inessential because the volume (size) of each melt is small, and the melts solidify very rapidly. These two factors also rule out the chemical fractionation of the lunar regolith by impact melting, proposed in ref. 6.

Meteoroid bombardment, however, can have a decisive effect on the process of volatilisation of Na, K and other elements from solid particles in the regolith, crushing and intermixing them. If this process really occurred (and occurs at present) on the Moon, then a chemical analysis of lunar rocks of the appropriate sizes could reveal the presence of a volatile-element concentration gradient.

Finally it should be noted that the approach we suggest may be also useful for solving some terrestrial ecological problems like that in ref. 7.

We are grateful to Dr G. A. Leikin for stimulating discussion on this subject.

Concentrations of dissolved copper in the eastern Atlantic Ocean 23°N to 47°N

CONSIDERABLE uncertainties still exist as to the abundances of most of the trace metals in seawater, including some of the more intensively investigated elements. Recent analyses of copper in surface waters south of New Zealand¹ and in waters from various depths over the East Pacific Rise² have given values of 0.06–0.40 $\mu\text{g l}^{-1}$, and a similar range has been found by M. J. McCartney (personal communication) for samples from the Mediterranean Sea and the north-eastern Atlantic Ocean. A geometric mean concentration of 0.26 $\mu\text{g l}^{-1}$ has been reported for samples collected off the shelf west of Scotland³. These values are either below

or at the lower end of the ranges reported for seawater by other workers. For example, extensive measurements⁴ of dissolved copper in surface waters have given average concentrations for various near-shore and open ocean regions which vary between 0.3 and 1.7 $\mu\text{g l}^{-1}$, with a mean of 0.8 $\mu\text{g l}^{-1}$, and a number of other recent investigations⁵⁻⁷ of North Atlantic Ocean waters also support an abundance value of $\sim 1 \mu\text{g l}^{-1}$. These contrasting findings may reflect real environmental variability but the alternative explanation that such variations are, at least in part, attributable to analytical problems, and especially to contamination, must also be considered. This communication reports values for dissolved copper in samples taken from the eastern Atlantic Ocean in October and November, 1975, which support findings of concentrations of $\sim 0.2 \mu\text{g l}^{-1}$. The results of measurements on these samples of the organically associated copper are summarised.

Surface samples were collected from RRS Discovery from a position forward of any discharges from the moving ship, using a plastic bucket with no metallic parts. Subsurface samples were collected using plastic water bottles. Metallic surfaces on the outside of these bottles, and the messengers employed, were coated with a plastic film. Samples collected from depths of < 500 m were filtered through Sartorius membrane filters of 0.45 μm average pore diameter, the filters having previously been leached with HCl. Samples from greater depths were not filtered since only a negligible amount of copper could be contributed from the small amounts of particulate material present. Dissolved copper was concentrated by uptake on Chelex-100 chelating ion-exchange resin after acidification of the sample (~ 800 ml) to pH 5, and the resin was eluted with 2 N nitric acid. The method was basically similar to that of Riley and Taylor⁸. This procedure leads to a measurement of the fraction of the dissolved copper which is available to the chelating resin. For the surface samples and a number of the subsurface samples from depths up to 1,000 m, analyses were also made on aliquots which had been photo-oxidised by ultraviolet irradiation for 5 h, using a 1,000-W medium pressure mercury arc lamp. The values obtained for the oxidised samples represent the total dissolved copper whereas the aliquots not treated in this way may contain some copper which is organically complexed in forms which are unavailable with this method of concentration. Further aliquots of most of these samples, also of ~ 800 ml, were extracted with chloroform at natural pH, without the addition of a complexing agent. The chloroform extracts were evaporated;

the residues were oxidised by evaporation with perchloric acid and redissolved in dilute nitric acid. Blank determinations were made for each procedure using only the reagents.

Concentration was commenced shortly after sample collection; the concentrates in dilute nitric acid were returned to the shore laboratory for determination of copper by atomic absorption spectrophotometry. Evaluation of the method has shown that the coefficient of variation of the procedure, as determined by analysing replicate samples at the level of 0.7 $\mu\text{g l}^{-1}$, is $\sim 4\%$; it gives essentially complete recovery of inorganic copper and the results agree closely with those obtained by solvent extraction of the complex formed with ammonium pyrrolidinedithiocarbamate. Blank values were 0.02 μg for the concentration procedure and $< 0.01 \mu\text{g}$ for the chloroform extraction.

The difference between the total and available dissolved copper fractions averaged $< 0.02 \mu\text{g l}^{-1}$ and so only the latter values are given in Table 1 with other chemical and hydrographic measurements; the samples were collected in sequence from north to south. The chloroform extractable fractions mostly ranged from undetectable to 0.02 $\mu\text{g Cu l}^{-1}$ with a single higher value of 0.04 $\mu\text{g l}^{-1}$. In coastal and estuarine waters, organically associated fractions of copper, operationally defined in ways similar to those used here, have been reported to be significant, ranging up to 50% or more of the total copper¹⁰⁻¹³. Our data indicate that in open ocean surface and intermediate waters, the fraction made available by oxidation of organic matter, and that which is chloroform extractable, each account for only $\sim 10\%$, or less, of the total copper. Measurements of operationally defined fractions do not enable any conclusions to be drawn as to the total extent of organic complexation. The difference in the magnitude of these fractions between coastal and oceanic waters, however, may reflect the different sources of organic complexing material in the near-shore and open ocean environments. The lower concentrations of such fractions in ocean waters, as found in this work, will require more sensitive analytical approaches for their fuller elucidation.

The concentrations of available dissolved copper ranged from 0.09 to 0.23 (mean 0.16) $\mu\text{g l}^{-1}$. This range agrees well with some other recent findings as discussed above but is substantially lower than the ranges reported hitherto for the North Atlantic Ocean⁴⁻⁷. For example, concentrations at various positions and depths in the eastern tropical region were found⁷ to range from 0.4 to 12.3 (mean 1.0) $\mu\text{g l}^{-1}$, while for a section from England to Barbados, extending

into the eastern Caribbean Sea¹, surface concentrations of 0.47–1.8 (mean 0.93) $\mu\text{g l}^{-1}$ were found.

Our values for surface waters show a general decrease from north to south over the latitudes concerned. Variations in concentration with depth were not pronounced but suggest a slight depletion in the euphotic zone relative to the deeper water. A comparison of the trends in the concentrations of dissolved silicon and copper in the vertical profiles (Table 1) provides, however, no evidence that transference into deeper water by biological processes is a major influence on the distribution of dissolved copper.

The authors thank the officers, crew and scientific complement of RRS Discovery on Cruise 75 for their assistance during this work. They are especially grateful to Dr S. E. Calvert and Mr C. I. Measures, and to Mr M. J. McCartney who provided the measurements of salinity and dissolved oxygen. The work was supported by the Natural Environment Research Council.

'Little Ice Age' palaeotemperatures from high altitude tree growth in S. Norway

THE sensitivity of tree growth to climate has led to reconstruction of past climates from long tree-growth records^{1,2}. Growth at the treeline in mountain regions and at the polar limits of tree growth is particularly useful because, in these locations, moisture is normally adequate and growth has been shown to be highly dependent on summer temperatures^{3,4}. Some other environmental factors have been recognised as influences on the growth of trees^{5,6}, but such factors are of relatively minor importance in this type of habitat. I reconstruct here a continuous record of summer temperature fluctuations representative of treeline conditions in the central southern Norwegian fjell since AD 1700. Combination of tree-ring data with information from glacier fluctuations over the same period shows short term oscillations of amplitude 1.0–3.0 °C superimposed on a long term increase in temperature of ~1.0 °C.

Two major limitations appear to restrict the use of tree-growth variations as palaeothermometers. First, even at the treeline, it is rare to be able to demonstrate a sufficiently high dependence of tree growth on summer temperatures. Secondly, calculation of standardised tree-growth indices (necessary to remove the effect of tree age on growth increment) results in the elimination of longer-term trends from the tree-growth record and hence the loss of information about longer-term temperature fluctuations. I show here that summer temperatures which are not subject to the above limitations can be reconstructed from tree growth. A Scots pine (*Pinus sylvestris*) tree-growth record, previously published by Slåstad⁷ from the treeline in upper Gudbrandsdalen (Fig. 1), and shown by him to be highly correlated with summer temperatures from Dombås meteorological station, is analysed for its palaeotemperature implications; independent glaciological and geomorphological evidence from the Storbreen glacier, Jotunheimen, is used to

Fig. 1 Location of Slåstad's tree-growth sites—Skjåk 6 (S6), Skjåk 7 (S7) and Nord-Fron 3 (N3)—the Storbreen glacier and Dombås meteorological station.

adjust the record to take into account the long-term change in climate over the period of interest. Slåstad's tree-growth data are shown in unaltered form and after smoothing by harmonic analysis⁸ in Fig. 2.

Based on mean monthly 2 p.m. temperatures from Dombås, Slåstad found the strongest relationship to be between tree growth and an index of June and July temperatures, with July weighted twice, that is $(1 \times \text{June} + 2 \times \text{July})/3$. This relationship has been checked and is illustrated and given in mathematical form in Fig. 3 for the 50-yr period 1901–50 and for two 25-yr subperiods. The correlation coefficient (r) for 1901–50 is $+0.77$ ($p=0.001$); for 1901–25, $r = +0.84$ ($p = 0.001$); for 1926–51, $r = +0.79$ ($p = 0.001$). This relationship between tree growth and summer temperature is considered sufficiently strong to use regression of summer temperature index on tree-growth as part of the basis for reconstruction of temperatures before AD 1900. Before the relationship can be extrapolated into the past any long-term trend in tree growth and climate must be obtained from independent evidence.

Liestøl, working on the Storbreen glacier, has calculated the mass balance of the glacier since AD 1816 (ref. 9) and working on the glacier-foreland, I have reconstructed former glacier margin positions back to AD 1750. This information has been used to estimate the tree growth corresponding to the glacier in equilibrium (that is, no net change in the glacier mass budget and hence no net movement of the glacier margin) from AD 1700 to 1950. The resulting line corresponding to the equilibrium condition of the glacier (EE') is shown in Fig. 2b but full details of the methods used are given by J. A. Matthews, unpublished. Tree growth of less than the indicated critical value corresponds to a glacier advance; glacier retreat is indicated when tree growth exceeds the critical value. Fig. 2b shows that Storbreen was in equilibrium at a lower tree-growth value in the recent past than in earlier times.

The close agreement between glacier fluctuations and tree-growth variations is explicable in terms of similar summer temperature dependent models for tree growth at the tree line and for glacier behaviour^{4,12–14}. The altitude of the equilibrium line, the line dividing the glacier into accumulation and ablation zones, is a climate-sensitive parameter and is particularly influenced by summer temperature^{15,16}. Establishment of the altitudinal displacement of the glacier equilibrium line permits calculation of the temperature difference between the temperature necessary to maintain the present glacier in equilibrium and the temperature that was necessary in ~ AD 1750 (when Storbreen reached its 'Little Ice Age' maximum extent¹⁰). The altitude of the steady-state equilibrium line necessary to maintain Storbreen in equilibrium at present (1949–63) has been established as 1,690 m (ref. 9). Assuming a constant ratio between the accumulation and ablation areas on the glacier in the equilibrium condition, the AD 1750 steady-state equilibrium line was 65–70 m lower than the present (1949–63) steady-state

Fig. 2 Graphical representation of the variation in tree growth over the past 250 yr (a) and the smoothed curve after harmonic analysis (b). The smoothed curve is calibrated using an index of summer temperatures, $(1 \times \text{June} + 2 \times \text{July})/3$ and is expressed as differences from the present (1949-63). The line (EE'), which represents the tree-growth value corresponding to Storbreen in the equilibrium condition, was used in the calibration as explained in the text.

line (J. A. Matthews, unpublished). Thus the temperature necessary to maintain the glacier in equilibrium in AD 1750 was $\sim 0.47^\circ\text{C}$ lower than the temperature necessary to maintain equilibrium at present (assuming summer temperature dependence of the equilibrium-line altitude and a summer vertical temperature gradient of 0.7°C per 100 m). On average, between 1949 and 1963, the mean equilibrium line¹⁷ has been ~ 75 m higher than the steady-state line⁹. This means that a fall in temperature of $\sim 0.53^\circ\text{C}$ would be necessary for the present glacier to be in equilibrium and also that in AD 1750, when the glacier was in equilibrium, temperatures were $\sim 1.00^\circ\text{C}$ below present.

The information derived from equilibrium-line displacement permits calibration of the tree-growth variations in terms of summer temperatures. The calibrated curve (Fig. 2b) provides

Fig. 3 The relationship between the summer temperature index, $(1 \times \text{June} + 2 \times \text{July})/3$, and tree growth for the period 1901-50 (—). Relationships for the subperiods, 1901-25 (○) and 1926-50 (●), are also shown (---).

a continuous record of summer temperatures over the past 250 yr. At least 10 major oscillations are indicated, superimposed on a long-term temperature rise of 1.0°C since AD 1750. Cool fluctuations reached 1.0 – 2.0°C below present; warm fluctuations were up to 1.0°C above present temperatures. These temperature fluctuations are regarded as irregular rather than cyclic, although recent work based on the Grampian Mountains, eastern Scotland¹⁸ has suggested the existence of cyclic patterns in growth of Scots pine during the twentieth century.

A brief description of summer temperature changes, reconstructed from tree growth in 25-yr periods since AD 1700, is summarised in Table 1. The first half of the eighteenth century

Table 1 Summer temperatures reconstructed from tree growth during 25-year periods. The temperatures are based on the index $(1 \times \text{June} + 2 \times \text{July})/3$ and are expressed as differences from present (1949-63).

Date (AD)	Index ($^\circ\text{C}$)
1701-1725	-1.63
1726-1750	-1.14
1751-1775	-0.48
1776-1800	-0.87
1801-1825	-1.15
1826-1850	-0.46
1851-1875	-0.55
1876-1900	-0.43
1901-1925	-0.28
1926-1950	-0.34

is shown to have been at least 1.0°C cooler than the present, particularly early in the century when, from 1701-25, summer temperatures were on average 1.6°C below present. In contrast, the period 1751-75 was markedly warmer ($<0.5^\circ\text{C}$ below present) and corresponds well with the retreat of Storbreen and other southern Norwegian glaciers¹⁹ from their 'Little Ice Age' maxima reached \sim AD 1750. Renewed cooling occurred near the end of the eighteenth century (1776-1800) and continued into the nineteenth century (1801-25), but this cooling phase was not as great as that experienced at the beginning of the eighteenth century. Since 1825 no period has been $> 0.6^\circ\text{C}$ below present temperatures; 1825-1900 was from 0.4°C to 0.6°C cooler than at present and the twentieth century (1901-1950) is indicated as being warmer

than any previous 50- or 25-yr period with summer temperatures that were on average only 0.3 °C below those of 1949–63.

The temperature fluctuations that have been inferred from tree-growth variations are in broad agreement with and supplement existing knowledge from other sources such as instrumental records, stable isotope ratios in ice and wood, treeline fluctuations, glacier fluctuations, the extent of Arctic pack-ice, fluvio-glacial sedimentation rates, the incidence of rockfalls, avalanches and other natural disasters, vine harvest dates and crop failures^{19–25}. The continuous nature of the tree-growth record and the proximity of treelines to glaciers in many geographically separate localities should enable application of similar approaches in other areas and a contribution to be made to knowledge of recent climatic changes in time and space.

Mass spectrometric studies of binding energies for nitrogen bases of nucleic acids *in vacuo*

FOR an understanding at the molecular level of the stability and interactions of nucleic acids, including the mechanisms of mutational events, the thermodynamic characteristics of base-pair formation must be determined¹. The most fundamental expression of these characteristics relates to the interaction *in vacuo*. We describe here the measurement of binding enthalpy of a single base pair from various combinations of bases *in vacuo*. We used pyrimidine bases methylated at the 1 position and purine bases methylated at the 9 position. As expected^{2,3}, the results obtained differ appreciably from those of earlier experiments⁴ on solutions, involving indirect methods of observing base pairing.

We have developed a direct method using mass spectrometers with a field ionisation source⁵. The field ionisation mass spectra contained peaks which could be attributed to ionised monomers and dimers only. The peak intensity was proportional to the concentration of the corresponding component near the field emitter. If concentrations are represented by $[M]$ for molecule and $[I]$ for ions then for the case of uracil and its dimer

$$[I_{uu}] = k_{uu}[M_{uu}]; [I_u] = k_u = [M_u]$$

where k_{uu} , k_u are ionisation efficiency factors.

k_{uu} = association constant =

$$\frac{[M_{uu}]}{[M_u]^2} = \frac{[I_{uu}]}{[I_u]^2} \frac{(k_u)^2}{k_{uu}} = \frac{[I_{uu}]}{[I_u]^2} k_1^*$$

k_1^* can vary from one experiment to another due to a change in the source geometry and emitter temperature.

In the temperature range studied, the temperature dependence of k_1^* is negligible. Figure 1 shows temperature dependence of the molecular ion peak intensity I^+ for cytosine, curves 1 and 2 based on electron impact and field ionisation measurements, respectively. The molecular beam was emitted from the orifice of a small Knudsen chamber (Fig. 1, ref. 5), its intensity being proportional to the saturated vapour pressure in the chamber. The heat of sublimation H_s is given⁶ by

$$\frac{d \ln(I^+T)}{d(1/T)} = \frac{-H_s}{R}$$

as 33.8 ± 0.5 kcalorie per mol by both measurements (curves 1 and 2, Fig. 1). On the other hand, the quartz resonator data which do not involve ions⁷ give a value calculated from

$$\frac{d \ln(v \times T^1)}{d(1/T)} = \frac{-H_s}{R}$$

of 34.1 ± 0.3 kcalorie per mol. The agreement between all three values supports the validity of the treatment.

Thus the base-pair binding enthalpy, ΔH , can be found from the temperature dependence of the association constant

$$\frac{d \ln K}{d(1/T)} = \frac{\Delta H}{R} \quad (1)$$

It is, however, necessary to confirm that binding energy determined in this way corresponds to the specific hydrogen bonds responsible for the complementary interaction⁸. The field mass spectra of 1-methyl-U and of dimethyl-U and T are shown

Fig. 1 $\ln I^+(1/T)$ and $\ln v(1/T)$ for 1-methylcytosine derived from measurements by: 1, electron impact; 2, field ionisation; 3, quartz resonator method. v , Vapourisation velocity.

Fig. 2 Field ionisation mass spectra for 1-methyluracil (U_1); 1,3-dimethyluracil ($U_{1,3}$); 1,3-dimethylthymine ($T_{1,3}$). Evaporator temperature was 40 °C for the first and 30 °C for the second samples. Scale factor given for each peak.

in Fig. 2. In the latter two cases hydrogen bonds cannot be formed, and the peaks $2M^+$ are not observed in spite of the almost three times greater concentration of monomers at the emitter. The height of the $(M+1)^+$ peak for doubly methylated bases agrees well with the carbon isotope composition⁸, while for U_1 protonated ions were also observed, indicating that the proton of the 1-nitrogen atom participates in pairing.

The base-pair lifetime of 10^{-8} s (ref. 8) at $t = 25$ °C is much longer than the escape time of the ion from the ionisation zone (10^{-12} s) (ref. 9). Thus base pairing precedes ionisation and occurs between neutral molecules.

Table 1 Enthalpies of base-pair formation

Base pair	$-\Delta H^*$ (kcalorie mol ⁻¹)	$-\Delta H$ (kcalorie mol ⁻¹)		
		(2)	(3)	(4)
AU	14.5	7.21	—	6.2 ± 0.6
UU	9.5	5.42	—	4.3 ± 0.4
AT	13.0	7.0	7.7	—
TT	9.0	5.21	—	—
GC	21.0	16.79	21.4	$10 - 11.5$
CC	12.0	13.72	—	6.3

*The experimental error in ΔH is ± 1 kcalorie mol⁻¹.

The temperature dependence of the association constants in molecular beams of GC and AT is shown in Fig. 3. The curves for AU are similar. The binding energy is found from the slopes of the van't Hoff plots (Fig. 3). The temperature dependence of the relative association constant for the base pairs, observed in the same experiment, is particularly relevant because this is essentially independent of variable factors. This therefore gives a more reliable difference between binding energies for the base pairs in question than the absolute values. The difference so found is -8.5 kcalorie per mol for GC and CC, -5.5 kcalorie per mol for AU and UU and -5.0 kcalorie per mol for AT and TT.

The values of binding energies for various base-pair combinations are summarised in Table 1. The canonical GC pair can be seen to be more stable than the CC pair, while AU and AT are similarly stronger than UU and TT. When our binding energies are compared with theoretical predictions^{2,3}, the agreement is quite good for GC and CC pairs, while the experimental data for pairs containing A, U and T bases are a factor of 1.7 higher than predicted. Our binding energies for pairs *in vacuo* are about double those for bases interacting in chloroform⁴, in which, however, association is weaker than in the inert solvent carbon tetrachloride¹⁰.

Fig. 3 van't Hoff plots for base-pairing associations: 1, GC; 2, CC; 3, GC-CC; 4, AT; 5, TT; 6, AT/TT.

The relative stabilities of base pairs determined previously⁶ are

This sequence agrees also with the results of dielectric measurement in non-polar solvents⁸, for example at 25 °C in benzene we have

(association constants 3×10^4 , 1.2×10^5 , 150, 28, 15, 8 mol⁻¹, respectively). It is interesting that the extrapolation of the plots in Fig. 3 down to 25 °C yields 10^3 and 40, which agree well with the relative association constants calculated from series (3). Thus our experimental method introduces no appreciable systematic errors.

Comparison of the experimental stability series (2) with theory shows good agreement⁸. The only exception is the CC pair, because according to theory, it should be more stable than the heteroassociates AU and AT. The discrepancies between the stability series (3), and the last column in Table 1, indicating that CC is at least of the same stability as AU and AT, suggest that the binding energy for CC requires further investigation.

Future experiments are expected to yield more accurate enthalpies of pairing of nitrogen bases *in vacuo* as well as data for other base-pair combinations which are important to an understanding of many problems concerning intermolecular and intramolecular interactions in nucleic acids.

We thank Professor B. I. Verkin for assistance and interest.

Interaction of heterocellular hereditary persistence of foetal haemoglobin with β thalassaemia and sickle cell anaemia

In normal adults a small amount of foetal haemoglobin (HbF) is detectable in up to 8% of the red cells (F cells)^{1,2}. In several inherited conditions, which include the Swiss³ and British⁴ types of hereditary persistence of foetal haemoglobin (HPFH), the proportion of F cells is increased in otherwise haematologically normal adults. It has been suggested (S. H. Boyer *et al.*, unpublished) that these conditions should be referred to as heterocellular HPFH to distinguish them from the more well known types of HPFH in which HbF is distributed throughout all the red cells (pancellular HPFH). Here we present evidence that the interaction of a gene for heterocellular HPFH with that for either β thalassaemia (β^{thal}) or sickle cell haemoglobin (HbS) results in the production of significantly greater amounts

of HbF than is usually found in β thalassaemia or sickle cell anaemia alone. The increased output of HbF which results from this interaction reduces the clinical severity of these common disorders. It seems that the genetic determinant for heterocellular HPFH is linked to the $\gamma\delta\beta$ -gene complex.

We have studied three families in which at least one member is a β^{thal} heterozygote with an unusually high level of HbF. The pedigrees of these families, together with the HbF, HbA₂ and F cell values of individual family members, are presented in Fig. 1. Detailed haematological data will be presented elsewhere (W.G.W. *et al.*, unpublished).

The proband of family M, of Italian origin, is a β^{thal} heterozygote with an atypically high HbF level. Her father has typical β^{thal} trait with the slight increase in HbF commonly found in that condition⁵; and both her mother

Table 1 Segregation of heterocellular HPFH and β^{thal} or β^{s} genes among the offspring of double heterozygotes

Family	β -chain marker	Offspring		ref.
		Parental type	Recombinants	
1	β^{thal}	2	0	11
2	β^{s}	2	1	12
3	β^{s}	7	0	13
4	β^{s}	3	0	14
S	β^{s}	8	1	This report
W	β^{thal}	5	1	This report
Total		27	3	

The excess of parental types indicates that the two genes are linked, with three recombinants (family 2, III.2, family S II.3, family W II.1) out of 30 informative offspring.

and brother, who are haematologically normal, also show a slightly increased HbF level and have elevated numbers of F cells of 12.9% and 12.1%, respectively. These latter individuals thus seem to be heterozygous for heterocellular HPFH; it is possible, therefore, that the high level of HbF observed in the proband results from the interaction of the gene for heterocellular HPFH with the β^{thal} gene.

The proband in family S, of Indian origin, has the haematological characteristics of sickle cell- β thalassaemia. Her haemoglobin consists of 68% HbS, 4% HbA, 2.9% HbA₂ and 24% HbF. The HbF is heterogeneously distributed among 73% of the red cells. This value for HbF greatly exceeds that normally found in sickle cell- β thalassaemia. Similar findings were observed in three siblings. The mother has typical β^{thal} trait, whereas the father has the sickle cell trait but also has an increased level of HbF and of F cells. It seems, therefore, that the proband and her three affected siblings have received the HbS and heterocellular HPFH genes from the father and the β^{thal} gene from the mother. The interaction of the three genes have produced a form of sickle cell- β thalassaemia with unusually high levels of HbF. None of these individuals has experienced the clinical symptoms usually associated with this disorder^{3,6}.

The proband of family W, of West Indian Negro origin, has the high HbF- β^{thal} trait, as does one of her children. Five other children have increased numbers of F cells, in four cases associated with increased levels of HbF. Her husband is normal.

In each of these families it seems, therefore, that a gene for heterocellular HPFH (probably identical to that previously described as Swiss HPFH, ref. 3) is segregating. It interacts with the β^{thal} gene to produce levels of HbF in the 6–15% range, and with the β^{thal} and HbS genes to produce HbF levels as high as 25%. How might this interaction result in such high levels of HbF? There is good evidence that, in patients with β thalassaemia or sickle cell anaemia, cells which contain HbF preferentially survive in

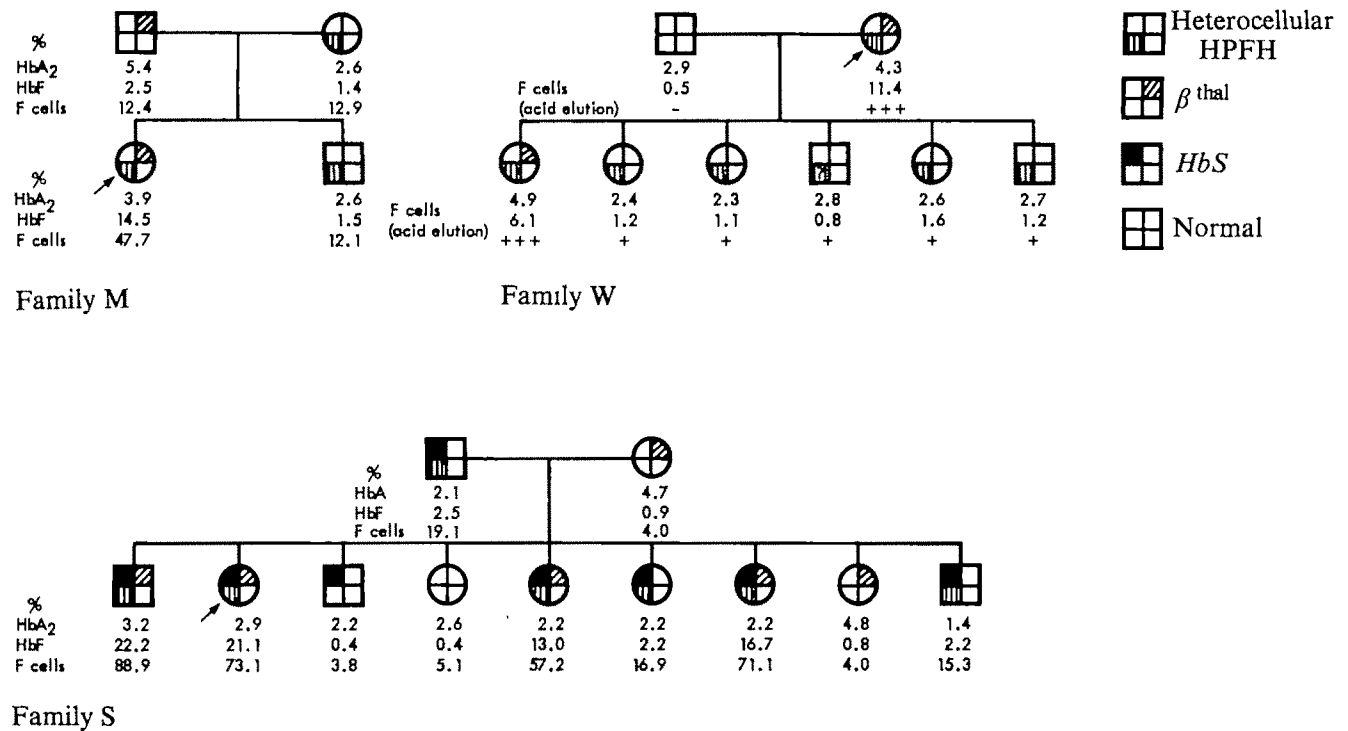

Fig. 1 Pedigrees of three new families in which the gene for heterocellular HPFH is segregating together with that for β thal or HbS. HbA₂ levels were determined by cellulose acetate electrophoresis⁶, the proportion of HbF was measured by alkali denaturation¹⁷ (upper limit of normal 0.9%), and F cells were measured by immunofluorescence⁸. For family W, semiquantitative estimates of F cell numbers were made in a separate laboratory, using the acid elution technique¹⁸. The genotype of individual II.4 in family W remains in doubt since although his HbF level fell within the normal range, he has more F cells than are found in normal individuals.

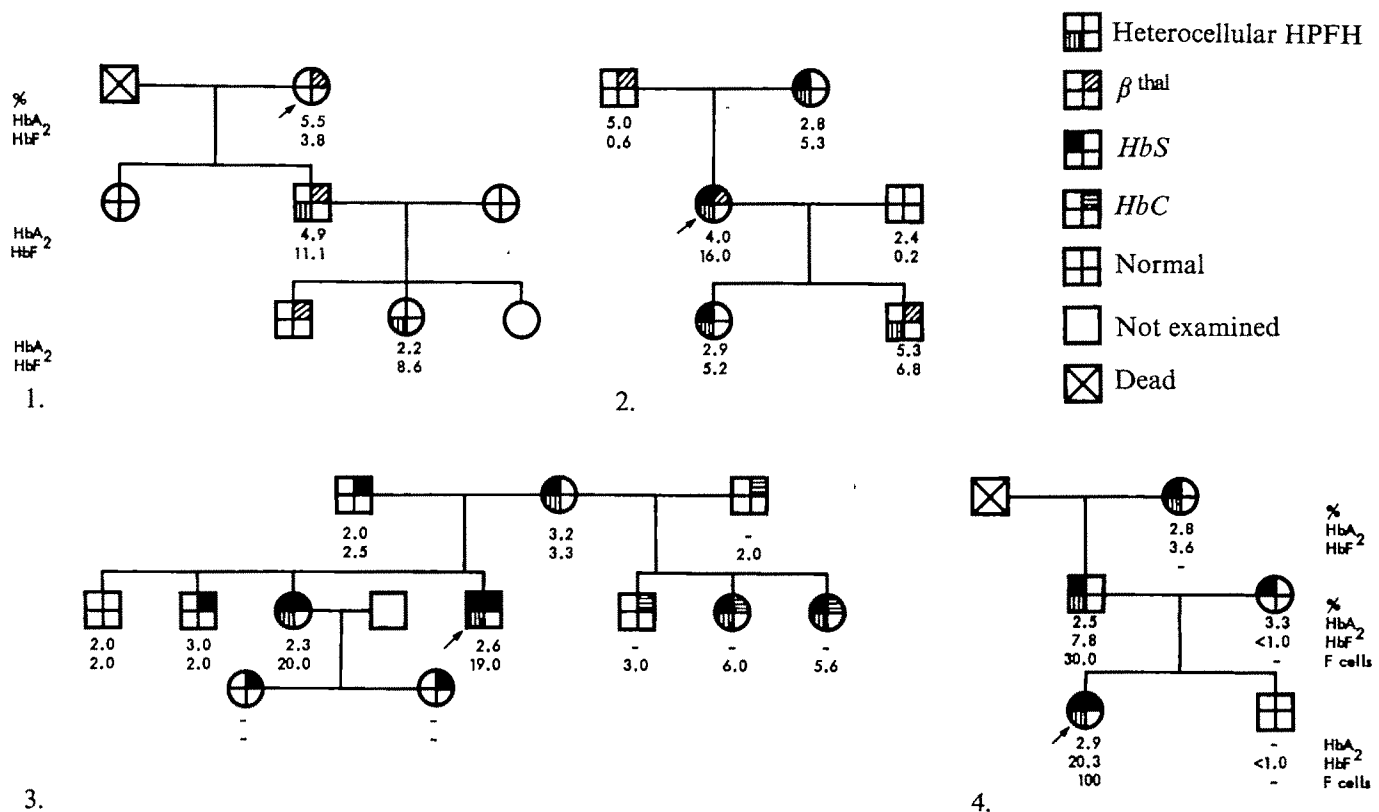

Fig. 2 Pedigrees of four families, previously reported¹¹⁻¹⁴, redrawn to show the interaction of heterocellular HPFH with HbS and/or β thal. The normal range for HbF in some of these reports may be as high as 2.5%. The distribution of HbF in the two HbS homozygotes in family 3 was described as homogeneous¹³. However, the difficulties involved in interpreting the results of the acid elution test¹⁸, and the fact that with 20% HbF most cells should contain HbF, suggest that the high HbF HbS homozygotes in this family can also be interpreted as due to the interaction of heterocellular HPFH with HbS.

the bone marrow or peripheral blood, respectively^{7,8}. It has been suggested that the elevated levels of HbF found in these conditions result from selective survival of the F cell population^{9,10}. If, therefore, in addition to the β^{thal} or HbS genes, there is a gene for heterocellular HPFH increasing the size of the F-cell pool on which the selective processes can act, a high level of HbF should occur. If this is the case, the level of HbF attained will depend on the degree of selection of the F-cell population and therefore on the severity of the condition. The finding of higher levels of HbF in the sickle cell- β thalassaemia heterozygotes than in the β^{thal} heterozygotes is fully in keeping with this prediction.

At least four other families in which it seems that interactions have occurred between the heterocellular HPFH gene and either the β^{thal} or the HbS genes, have been reported previously¹¹⁻¹⁴. Pedigrees of these families, modified according to this interpretation, are shown in Fig. 2. Genetic analysis of these families, together with those which make up the present report, indicate that the gene for heterocellular HPFH is inherited as an autosomal dominant. Furthermore, because the seven families have genes for both heterocellular HPFH and either β^{thal} or HbS segregating, it is possible to test for linkage of the gene for heterocellular HPFH to the β^{thal} or HbS genes. In this analysis we assume that the β^{thal} gene is very closely linked, if not allelic, with the β -structural gene since only one doubtful crossover has been observed in 62 offspring of informative matings⁸. The results, shown in Table 1, indicate that there is a large excess of parental types over recombinants among the offspring and provide good evidence that the gene for heterocellular HPFH is linked to the $\gamma\delta\beta$ -globin gene complex. The frequency of recombination between the gene for heterocellular HPFH and the β -structural gene, three out of 30, compares with no recombinants observed between the δ - and β -structural loci out of 63 offspring of informative matings¹⁵, and at least one, and possibly 3, recombinants between the β^{thal} and δ -structural loci out of 58 informative offspring¹⁶.

The action of the gene for heterocellular HPFH seems to increase the number of F cells rather than the amount of HbF per cell, since there is a linear relationship between the number of F cells and the level of HbF, both in normal adults and in those with heterocellular HPFH (W.G.W. *et al.*, unpublished). Although nothing is known of the mechanism by which this is brought about, it is intriguing that such a controller gene should be linked to the $\gamma\delta\beta$ -structural gene complex. In all these families the gene for heterocellular HPFH has been found *cis* to the β^{thal} gene and *trans* to the β^{thal} gene. We would predict that there should be a marked survival advantage in having the gene for heterocellular HPFH linked *cis* to the β^{thal} locus. The advantage which the β^{thal} gene has in malarious areas would then be maintained without loss of β^{thal} genes in the homozygous state since they would be protected by the high levels of HbF. The mild clinical condition of the HbS homozygotes^{13,14} and HbS- β^{thal} compound heterozygotes¹², who also carry the gene for heterocellular HPFH, confirm these predictions. It will be of great interest to study patients with sickle cell anaemia or homozygous β thalassaemia who have unusually mild courses and high levels of HbF, to determine whether they represent further examples of the interaction of the gene for heterocellular HPFH with these conditions. Such a project is already under way in Saudi Arabia where the Shiite Arab HbS homozygotes have a very mild sickling disorder due to the presence of 15-30% HbF (ref. 16).

The study of heterocellular HPFH is of considerable practical importance because it is clear that if it were possible to increase the F-cell population in patients with sickle cell anaemia or β thalassaemia, the clinical severity of these disorders would be reduced.

We thank Drs T. J. Hamblin, J. H. Edwards and A. M. Barlow for referring these families to us. This work was supported by the MRC.

Chromosome 21 does not code for an interferon receptor

It is well established that human cells which are trisomic for chromosome 21 are more sensitive to the antiviral activity of interferon than normal diploid cells¹⁻⁴. If chromosome 21 codes for an interferon receptor site localised at the cell surface, as suggested^{4,5}, one might expect cellular binding of interferon to increase in the order monosomic 21 cells, disomic 21 cells and trisomic 21 cells. This did not prove to be the case. All cell types bound interferon equally well. In view of these and previously⁶ reported data, it is postulated that chromosome 21, if it codes for a protein involved in the interferon response of the cells, does not specify the receptor molecule *per se* but another molecule that is involved in the processing of the antiviral message from the cell surface to the interior of the cell.

Human interferon, whether induced by viruses, double-stranded RNA or phytohaemagglutinin in either leukocytes, fibroblasts or lymphoblasts, seems to elicit a higher antiviral response in human skin fibroblasts which are trisomic for chromosome 21 (T-21) than in cells which are disomic for chromosome 21 (D-21); D-21 cells are in turn more sensitive to the antiviral action of interferon than cells which are monosomic for chromosome 21 (M-21)¹⁻⁶. To account for the increased interferon sensitivity of T-21 cells, different hypotheses have been proposed. According to Tan^{1,2}, chromosome 21 governs the synthesis of a secondary antiviral protein, whereas Chany⁴ postulated that chromosome 21 would carry the structural genes for an interferon receptor. From studies with interferon covalently bound to an insoluble matrix it was inferred that the interferon receptor site may be located at the outer cell membrane⁷⁻¹⁰. That such a receptor site could be specified by chromosome 21 was suggested by Revel *et al.*⁵. They found that an antiserum against a chromosome 21-directed cell-surface component reduced markedly the antiviral action of interferon in normal human diploid cells.

Fig. 1 Inhibition of CPE in T-21, D-21 and M-21 fibroblast cultures exposed to human leukocyte interferon (100 IU ml^{-1}) for varying times (as indicated in the abscissa) and challenged at 24 h with VSV. Human fibroblast cultures, which were either trisomic for chromosome 21 (T-21) (designated SCH), disomic for chromosome 21 (D-21; designated VGS) or monosomic for chromosome 21 (M-21; designated GM-230), were grown to confluency in Eagle's MEM+10% FCS in micro Linbro plates. When confluent, the cells were exposed to 100 IU ml^{-1} human leukocyte interferon (in Eagle's MEM+3% FCS) for either 1, 3, 10, 30 or 60 min, or 2, 4, 8 or 24 h. After incubation with interferon the cells were drained, washed and further incubated with Eagle's MEM+3% FCS. At 24 h all cell cultures were challenged with 100 CCID₅₀ (cell culture infecting dose 50) of VSV and viral CPE readings were made as soon as CPE reached 100% in the virus controls: this was, for a large number of experiments, at 1 d in GM-230 cells, at 2 d in VGS cells and at 2–3 d in SCH cells. □, T-21 (SCH); ●, D-21 (VGS); △, M-21 (GM-230).

If chromosome 21 indeed codes for the interferon receptor, one may expect T-21 cells to be more sensitive to all activities of interferon, both antiviral and non-antiviral. Our data indicate, however, that, unlike the antiviral activity, the non-antiviral effects of interferon "priming" and "toxicity enhancement" are not better expressed in T-21 than in normal diploid cells. These findings are difficult to reconcile with an interferon receptor coded for by chromosome 21, unless one assumes the existence of two (or more) interferon receptor sites, one of which is responsible for the antiviral state and is controlled by chromosome 21, and a second one which is not determined by chromosome 21 and mediates (some of) the non-antiviral effects of interferon.

If the assumption that chromosome 21 codes for an interferon receptor is correct, one might expect cellular binding of human interferon to increase in the order M-21, D-21 and T-21, the more since binding of interferon to the cells seems to be related to the antiviral and anticellular action of interferon in these cells^{11–13}. Therefore, cell binding of interferon was examined with M-21, D-21 and T-21 cells, and, to minimise nonspecific binding, the cells were exposed to interferon for a limited time period (30 min). In concomitant experiments it was ascertained that such short incubation enabled part of the antiviral potency of interferon to be expressed.

The sources of human leukocyte and fibroblast interferon were the same as those referred to previously¹. All human fibroblast cultures were derived from skin biopsies. The monosomic 21 lines (designated GM-137 and GM-230) were obtained from the Mammalian Genetic Mutant Cell Repository (Camden, New Jersey). The latter cell lines were also employed in Tan's studies². All cell cultures were matched as nearly as possible with regard to the number of cell generations in culture.

To measure resistance to virus infections, cells are generally incubated with interferon for a 18–24-h period before virus challenge. In such conditions T-21 fibroblasts are more

sensitive to the antiviral action of interferon than normal diploid fibroblasts, which are in turn more sensitive than M-21 fibroblasts^{2,4}. When the time of exposure of interferon to the cells was shortened, interferon activity gradually diminished (Fig. 1). Irrespective of the time the cells were left in contact with interferon before virus challenge, T-21 cells proved invariably more sensitive to the antiviral activity of interferon than D-21 or M-21 cells—for example, a 30-min exposure of T-21 cells to 100 IU ml^{-1} of interferon afforded nearly complete protection against the cytopathic effect of vesicular stomatitis virus (VSV). To attain a similar protection in D-21 and M-21 cells, an 8-h interferon treatment was required (Fig. 1). Contrary to what may have been expected from a gene dosage effect², M-21 and D-21 cells were equally sensitive to the antiviral action of interferon (Fig. 1). It should be pointed out that viral cytopathic effect (CPE) developed faster in M-21 than in D-21 cells (whether the differences in rate of CPE development reflect differences in the kinetics of virus multiplication is now being studied). Therefore, CPE readings were made at an earlier time for M-21 than for D-21 and T-21 cells. This may explain the differences between our results and those of Tan², who estimated viral RNA synthesis for all cell types at the same time (8 h after infection).

In T-21 cells, the same interferon titre was attained whether the cells were inoculated with VSV 24 h or immediately after a 30-min interferon treatment. Such a short interferon pulse, whether carried out at 37 (Table 1) or 4 °C (data not shown) resulted in the expression of 3–10% of the total interferon activity in T-21 cells and 0.3–1% of the total interferon activity in M-21 and D-21 cells (Table 1). Again, in conditions in which virus challenge was applied immediately after a 30-min interferon treatment, no significant differences were observed in the behaviour of D-21 and M-21 cells. Thus, no gene dosage effect² could be observed in our assay conditions.

Human fibroblast cultures derived from old donors behave very much like T-21 cells in their sensitivity to the antiviral action of interferon¹⁴. The differential sensitivity

Table 1 Interferon titre expressed in various T-21, D-21 and M-21 fibroblast cultures exposed to human leukocyte interferon or human fibroblast interferon (10^4 IU ml^{-1}) for 30 min at 37 °C, and then challenged immediately with VSV

Cell type	Designation	Interferon titre ($\log_{10} \text{ IU ml}^{-1}$)	
		Leukocyte interferon	Fibroblast interferon
T-21	SCH	2.8 (2.5–3.0)	2.5
	BR	3.0	2.5
Old D-21	SW	2.5	2.3
	G	2.5	2.3
D-21	VGS	1.8 (1.5–2.0)	1.6 (1.5–1.8)
	VG ₂ S	2.0	1.5
M-21	GM-230	1.7 (1.5–2.0)	1.5
	GM-137	2.0	1.5

Human fibroblast cultures, which were either trisomic for chromosome 21 (T-21; designated SCH and BR), disomic for chromosome 21 (D-21) and derived from old donors (designated SW and G, both 80 yr old), disomic for chromosome 21 (D-21) and derived from young donors (designated VGS and VG₂S), or monosomic (M-21) for chromosome 21 (designated GM-230 and GM-137), and which had been grown to confluency in micro Linbro plates, were exposed to serial dilutions (in Eagle's MEM+3% FCS) of human leukocyte or fibroblast interferon stock preparations, both containing 10^4 IU ml^{-1} . The interferon incubation period was limited to 30 min at 37 °C. Immediately afterwards, the cells were washed and challenged with 100 cell culture infecting dose 50 (CCID₅₀) of VSV. The interferon titre was determined as the reciprocal of sample dilution inhibiting viral CPE by 50%. CPE readings were taken as soon as viral CPE in the control cell cultures reached 100%. The data show means for 3–10 experiments. The range of the individual values is indicated in parentheses.

Table 2 Binding of interferon to T-21, D-21 and M-21 fibroblast cultures exposed to human leukocyte interferon or human fibroblast interferon for 30 min at 37 °C

Interferon applied to the cells (log ₁₀ IU ml ⁻¹ per Petri dish)	Interferon recovered from culture medium (log ₁₀ IU ml ⁻¹ per Petri dish)			Interferon recovered from cells (log ₁₀ IU ml ⁻¹ per 5 Petri dishes)		
	T-21	D-21	M-21	T-21	D-21	M-21
Human leukocyte interferon						
3.0	2.8	2.8	2.8	1.2	1.2	1.0
4.0	3.6	3.6	3.3	1.4	1.4	1.3
5.0	5.2	5.2	5.2	2.7	2.5	2.5
Human fibroblast interferon						
3.0	2.5	2.2	2.5	1.0	1.0	0.7
4.0	3.4	3.3	3.3	1.2	1.1	1.0
5.0	4.5	4.5	4.5	1.5	1.7	1.3

Human fibroblast cultures, which were either trisomic for chromosome 21 (T-21; designated SCH), disomic for chromosome 21 (D-21; designated VGS) or monosomic for chromosome 21 (M-21; designated GM-230) and which had been grown to confluency in 60-mm Falcon Petri dishes, were exposed to human leukocyte or fibroblast interferon (10³, 10⁴ or 10⁵ IU ml⁻¹ in Eagle's MEM+3% FCS). The interferon incubation period was limited to 30 min at 37 °C. Immediately afterwards, the culture medium was collected for assay of residual interferon activity and the cell monolayer was washed three times with Dulbecco's PBS at 4 °C. The cells were then scraped off with a rubber policeman into 0.5 ml PBS per Petri dish, pelleted and resuspended with 1 ml PBS per 5 Petri dishes. Cell homogenates were prepared by ultrasonication for 20 s in a 100 W ultrasonic disintegrator MSE (operating at maximum output and at a nominal frequency of 20 KHz). These cell homogenates were assayed for interferon content. All interferon titrations were carried out using a VSV CPE inhibition assay in D-21 (VGS) cells. Approximate number of cells per Petri dish: 10⁶ (for T-21, D-21 and M-21 cells). Average protein content per Petri dish (determined by the Lowry method): 852 µg (range: 550–1,080 µg) for T-21, 985 µg (range: 640–1,240 µg) for D-21; and 625 µg (range: 520–720 µg) for M-21 cells.

of 'old' and young' diploid fibroblasts to the antiviral effect of interferon was also observed in the present experiments in which the cells were pulse-treated with interferon before virus challenge (Table 1).

The rapid action of human interferon in T-21 and old D-21 cells (Table 1) is reminiscent of the rapidly developing resistance to virus infection induced by interferon in what has been considered to be physiological conditions¹⁴.

Is the enhanced antiviral action of interferon in T-21 cells, as noted after a brief exposure of the cells to interferon, mediated by or, at least related to an increased binding of interferon to the cells? To assess this question, cell binding of interferon was examined in conditions which allowed a clear differentiation between the antiviral activities of interferon in T-21 and D-21 cells. Therefore, uptake of interferon by the cells was measured after a 30-min contact period at 37 °C. The amount of cell-bound interferon seems to reach a plateau after a 30-min incubation period¹⁵. Cell-associated interferon as well as residual supernatant interferon were quantified for T-21, D-21 and M-21 cells which had been exposed to various doses (10³, 10⁴ or 10⁵ U ml⁻¹) of either human leukocyte or fibroblast interferon. As shown in Table 2, very small amounts of interferon (0.01–0.1%) were taken up by the cells. The amounts of interferon taken up by T-21 cells did not differ markedly from the amount of interferon which became associated with either M-21 or D-21 cells (Table 2).

Thus, the increased sensitivity of T-12 cells to the antiviral action of a 30-min interferon pulse is not reflected by an increased binding of interferon to these cells. Such increased binding would have indicated an increased number of available interferon receptors and/or an increase in the affinity of such receptors for interferon. Provided that our data do not support the existence of an interferon receptor site coded for by chromosome 21, how could they be reconciled with the implication of a chromosome 21-specified cell surface component in the antiviral action of interferon? Hypothetically, the cellular component coded for by chromosome 21 is not the interferon receptor *per se*, but part of a molecular complex that is involved in the processing of the antiviral message from the cell surface to the interior of the cell. The regulator function of chromosome 21 would be required for the antiviral action of interferon, but not for its other effects such as "priming" and "toxicity enhancement"¹⁶. Since D-21 cells derived from old donors (ref. 14 and Table 1) and some other D-21 cells (for example, cells derived from cystinosis patients⁴) behave like T-21 cells in their sensitivity to the antiviral action of

interferon, whereas triploid cells (which are trisomic for all chromosomes) act like D-21 cells⁴, the question may even be raised as to whether chromosome 21 directly codes for any protein involved in the interferon response of the cells.

We thank Mr W. Zeegers, Mrs G. Koninckx and Miss F. De Meyer for assistance. This work was supported by the Fonds voor Wetenschappelijk Geneeskundig Onderzoek and the Fonds Derde Cyclus (Katholieke Universiteit Leuven).

Episome-like behaviour of donor DNA in transformed strains of *Neurospora crassa*

TRANSFORMATION is a well established process for the transfer of genetic information in bacteria^{1,2}. Although such a system in higher organisms remains to be fully elucidated, certain features of gene transfer in eukaryotes have similarities with bacterial transformation³. The occurrence of inositol-independent (*int*⁺) transformants has been reported in *Neurospora* when an inositol requiring (*int*⁻) mutant strain (89601) is treated with a wild-type (RL3-8A) DNA preparation^{4,5}. Although these transformants are stable for inositol independence (*int*⁺) during the somatic cell cycle they differ in the ability to transmit this character to their sexual progeny. Essentially there are two groups of transformants, one capable of Mendelian transmission

and another showing only a rare non-Mendelian transmission of the transformed character (*int*⁺) (Table 1). Such differences in modes of genetic transmission can be explained if the donor DNA exists as an episome in the transformed strains. Thus the physical status of the episomes determines the Mendelian and non-Mendelian transmission of the genetic character controlled by them. When integrated they are transmitted in a Mendelian way like any other chromosomal gene; whereas in the non-integrated (autonomous) form their nucleolytic degradation (or slow replication followed by segregation) during meiosis can lead to non-Mendelian transmission. This hypothesis is supported by demonstration of a continued aberrant transmission of the inositol independence to the sexual progeny in the subsequent generations³. Here we describe experiments which establish further the validity of the above hypothesis.

We used DNA-intercalating drugs to eliminate the non-integrated episomes from the transformed strains of *Neurospora*. Both ethidium bromide and acridine have been used

Table 1 Summary of the *Neurospora* strains used

Strains	Description
Wild type (RL3-8A)	No growth requirement for inositol (<i>int</i> ⁺)
Mutants (89601 a/A)	Require inositol for growth (<i>int</i> ⁻)
Transformants*	
Group I	
26-2	These strains show Mendelian transmission of the transformed character (<i>int</i> ⁺) to their meiotic progeny
165	
169	
Group II	
26-6	These strains are rarely able to transmit their <i>int</i> ⁺ character to their sexual progeny and thus show non-Mendelian transmission
166	
Others	
26-6-1	Require inositol for growth (<i>int</i> ⁻) and were obtained after treatment of the transformed strain 26-6 with ethidium bromide (10 µg ml ⁻¹)
26-6-2	
26-6-3	

*These strains were obtained as inositol-independent (*int*⁺) colonies after treatment of the mutant strain (89601) with the wild-type (RL3-8A) DNA preparation^{4,6}. These strains also carry another genetic marker (*os*⁻) and cannot grow on 1 M NaCl. Their origin has been described elsewhere⁵.

successfully to induce loss of autonomous episomes from bacteria⁷⁻⁹ and their mode of action is well known¹⁰⁻¹¹. The drug-induced loss of episomes in *Neurospora* would lead to the production of cells requiring inositol for growth; such *int*⁻ colonies can be detected easily in *Neurospora* by conidial analysis. When treated with these drugs, however, only transformants showing non-Mendelian transmission of the *int*⁺ character would be expected to yield *int*⁻ colonies, whereas the wild-type strain and the transformants showing Mendelian transmission would remain unaffected. Following this rationale, the different *int*⁺ strains of *Neurospora* were treated with the drugs. The results of the experiments presented here support the hypothesis of episome-like behaviour by the donor DNA in the *int*⁺ transformants.

The strains of *Neurospora crassa* used are described in Table 1. Cultures of *int*⁺ strains were treated with different concentrations (0–100 µg ml⁻¹) of ethidium bromide or acridine. The latter was a mixture of 2,8-diamino-10-methyl acridinium chloride and 2,8-diamino acridine (Sigma). The drug was added to a culture at its inception and each culture was then incubated for 4–5 d in the dark at 25 °C. The mycelial mat thus obtained was washed thoroughly and transferred to complete agar medium and allowed to conidiate by incubation for a further 4–5 d. Conidia from each culture were collected separately and plated on complete agar medium containing L-sorbose¹². The growing colonies were then isolated and tested for growth requirement by spreading on minimal medium and on medium supplemented with inositol (80 µg ml⁻¹). The colonies able to grow on minimal medium were scored as *int*⁺ (their

growth was not affected by the presence of inositol in the medium). Those which required inositol for growth and could not grow on the minimal medium were scored as *int*⁻. The frequency of production of *int*⁻ colonies was considered to be a direct measure of the drug-induced loss of the *int*⁺ determinants. The data presented in Tables 2 and 3 show that the drugs produced *int*⁻ colonies in significant numbers only from the transformants which showed a non-Mendelian transmission of the transformed character (that is group II). Ethidium bromide was effective in this respect on both strains 26-6 and 166 of this group (Tables 2 and 3). The data in Table 2 also suggest that the loss of inositol independence depended on the concentration of ethidium bromide. The frequency of production of *int*⁻ colonies increased linearly with increasing drug concentration (Table 2): 50 µg ml⁻¹ was found most effective, and approximately 8% of treated colonies were *int*⁻.

The effect of acridine was similar to that of ethidium bromide. The data in Table 3 show the production of *int*⁻ colonies in a significant number by the group II transformants (strains 26-6 and 166) treated with acridine. The effect of acridine also depended on the concentration of drug used (data not shown). The drug-induced loss of the *int*⁺ character among the group II transformants suggests that in these transformants the donor DNA exists as an autonomous episome (which can be eliminated by treatment with DNA-intercalating drugs).

For comparison, the group I transformants (that is, strains 26-2, 165 and 169) were treated with ethidium bromide and acridine. The data in Table 3 show that their inositol independence was unaffected by drug treatment; no colony which required inositol for growth was produced by such treatment. These data suggest that in the group I transformants the donor DNA (carrying the *int*⁺ genetic information) has been integrated into the recipient chromosome. As another control, the wild-type strain (RL3-8A) was treated with both of the drugs and, among a large number of the colonies examined, all were found to grow on minimal medium (Table 3). Thus the wild-type strain could retain its inositol independence (*int*⁺) after drug treatment as expected since the *int*⁺ genetic information is chromosomal in this strain. The fact that the inositol independence of the wild-type strain was not affected by the drug rules out the possibility of a mutagenic effect of the drug on other strains. Crosses were performed to establish the allelism of the newly isolated *int*⁻ strain (26-6-1, 26-6-2, and 26-6-3, Table 1) with the parental *int*⁻ strains (89601). The new *int*⁻ strain in crosses with 89601 (*int*⁻) produced only *int*⁻ progeny; not one wild-type progeny was detected even when more than a million spores were tested from each of these crosses. Also the new *int*⁻ strains in crosses with the wild-type strain were found to produce asci with four *int*⁻ and four *int*⁺ spores per ascus. These genetic data

Table 2 Ethidium bromide-induced loss of the inositol independence (*int*⁺) in a transformed strain (26-6) of *Neurospora crassa*

Drug concentration (µg ml ⁻¹)	No. and phenotype of colonies obtained after the drug treatment			Frequency of the colonies which lost <i>int</i> ⁺ character (%)
	<i>int</i> ⁺	<i>int</i> ⁻	Total	
0	886	0	886	0
1	500	0	500	0
5	494	6	500	1
10	581	17	598	2.9
20	473	27	500	5.4
50	459	41	500	8
100	463	37	500	7.5

The transformed strain 26-6 was treated with the different concentrations of ethidium bromide and the colonies obtained by the conidial analysis were examined for their growth requirement with respect to inositol (see text).

Table 3 Effect of drug treatment on the loss of inositol independence (*inl*⁺) among different strains of *Neurospora crassa*

Strains	No. and phenotype of colonies examined after treatment with Ethidium bromide* (10 µg ml ⁻¹)			Acridine* (15 µg ml ⁻¹)		
	<i>inl</i> ⁺	<i>inl</i> ⁻	Total	<i>inl</i> ⁺	<i>inl</i> ⁻	Total
Wild-type strain (<i>inl</i> ⁺) (RL3-8A)	2,560	0	2,560	2,700	0	2,700
Transformed strains (<i>inl</i> ⁺)						
(I) showing Mendelian transmission of the <i>inl</i> ⁺ character						
26-2	943	0	943	500	0	500
165	842	0	842	900	0	900
169	921	0	921	800	0	800
(II) Showing non-Mendelian transmission of the <i>inl</i> ⁺ character						
26-6	662	18	680	1,649	41	1,680
166	689	11	700	587	13	600

*The different inositol-independent (*inl*⁺) strains of *Neurospora* were treated with the drugs separately and then examined by conidial analysis as described in the text.

clearly establish that the *inl*⁻ phenotype of the drug-treated culture was determined by a Mendelian gene and that latter was allelic to the parental *inl*⁻ strain (89601).

An episome can exist inside the recipient cell in two distinct forms, the autonomous state and the integrated state¹³, and the data presented here are compatible with the hypothesis that donor DNA exists as an episome in the transformed strains of *Neurospora*. These data suggest the difference in the physical status of the donor DNA (carrying the *inl*⁺ genetic information) in the two groups of the *Neurospora* transformants. In the group I transformants the episome is chromosomal whereas in group II it is autonomous. Although acridines are known mutagens¹⁴, the effect of ethidium bromide and acridine reported here cannot be explained on the basis of a mutation at the *inl*⁺ locus in the transformants because these drugs did not produce *inl*⁻ colonies in the wild-type strain. Because the transformed strains were stable during their somatic cell cycle it seems that the donor DNA may exist as covalently closed circles to avoid nucleolytic digestion. These, however, could still be liable to digestion by restriction endonucleases during meiosis; the existence of such endonucleases in higher organisms has been invoked to provide the molecular basis of non-Mendelian inheritance in higher organisms^{15,16}. The frequency of elimination of episomes carrying *inl*⁺ genetic information in *Neurospora* was rather low (8%) compared with the high frequency of elimination (up to 100%) of F factors reported earlier¹⁷. These values in *Neurospora*, however, are comparable with that of the elimination of the drug resistance factors in bacteria¹⁸.

The data presented here imply certain similarities in the behaviour of episomes in prokaryotes and eukaryotes as suggested previously¹⁹. Some of the characteristics of genetic transformation in *Neurospora* described here have some parallels in other eukaryotes²⁰.

I am grateful to the late Dr E. L. Tatum for encouragement. I thank Drs R. D. Hotchkiss, S. F. H. Threlkeld and E. W. Caspari for helpful suggestions and critical review of the manuscript. I also thank Ms A. Lacombe for technical assistance. This work was supported by grants from the NIH and NSF.

Genetic polymorphism of C4 in man and localisation of a structural C4 locus to the HLA gene complex of chromosome 6

NATIVE C4, the fourth component of human complement (C4¹) has a molecular weight of 204,000 and is composed of three distinct polypeptide chains linked by disulphide bonds and non-covalent forces². C4 migrates as a β 1 globulin when subjected to electrophoresis in Agarose gel. Genetically determined structural polymorphism has been detected in the complement components C3 (refs 3 and 4), C6 (ref. 5) and properdin factor B (ref. 6). As well as their use in forensic science and population genetics, such polymorphisms are valuable tools for work on genetic linkage and chromosome mapping, as shown by the assignment of the factor B locus to chromosome 6, closely linked to HLA-B*¹⁸. We report here similar findings with human C4.

EDTA-plasma, heparin-plasma and serum were used initially. Samples were either studied within 2 h of collection or stored at -75 °C until examined. Serum proteins were separated by high voltage electrophoresis in Agarose gel⁹ for 1-1.5 h. C4 bands were then made visible by immunofixation with specific antibody¹⁰, and staining with Coomassie brilliant blue. Specific anti-C4 was produced by immunising rabbits with C4 purified by ion exchange chromatography, ammonium sulphate precipitation and preparative electrophoresis on polyacrylamide gel. This monospecific anti-C4 showed reactions of complete identity with anti-C4 obtained from Dr C. Alper, Boston, and also with commercial anti-C4 (Behring Institut and Atlantic Antibodies).

Ninety-three unrelated Norwegian adults have been studied. In 91 of them, one of three patterns was found: one slow (S) band only, one fast (F) band only, or the two together (FS) (Fig. 1). In two individuals a variant pattern was observed in which the ordinary F band occurred together with a band (M) localised between the position of

Fig. 1 The common C4 phenotypes revealed by immunofixation electrophoresis.

the S and F bands. These patterns could be reproduced in the same samples examined on different occasions, and in samples from the same individuals bled at different times. The patterns were identical in serum, EDTA-plasma and heparin-plasma when these were handled as described above.

The family data consist of 17 matings with 112 children. The families have been typed for approximately 20 other genetic marker systems, thus assuring a regular pattern of inheritance. Heparin-plasma samples stored at -75°C were typed and the results confirmed the postulate that the bands S and F observed in the material of unrelated adults represent the expression of two alleles $C4^S$ and $C4^F$ at one locus—that is a structural locus for C4 (Table 1).

Among 93 unrelated Norwegians the following gene frequencies were observed: $\sim 0.52 C4^S$, $\sim 0.47 C4^F$ and $\sim 0.01 C4^M$. Phenotype frequencies were in agreement with the expected Hardy-Weinberg distribution (23 C4S, 2 C4FM, 51 C4FS and 17 C4F). Preliminary findings with an extended population sample suggest the existence of other variant alleles.

Table 1 C4 types in 17 matings with 112 children

Mating type	No. of matings	No. of children	C4 types of children				
			S	FS	F	FM	MS
S \times FS	2	22	8	14			
S \times F	1	4		4			
FS \times FS	2	6		4	2		
FS \times F	9	60		25	35		
F \times F	2	8			8		
FS \times FM	1	12		3	2	3	4
	17	112	8	50	47	3	4

The heterogeneity of human C4 has been reported before^{11,12}, and has been postulated to have, at least in part, a genetic background. Gene frequencies, however, have not been reported, and no extensive family studies have been done. It is therefore difficult to assess whether this heterogeneity is related to the polymorphism described here.

The detection of a structural polymorphism gave us the opportunity to try and link the C4 locus to other loci of the human genome. In 85 HLA-B/C4 informative meioses there were no recombinations. This definitely proves that the two loci are closely linked, the recombination fraction being 0.0–4.3 (95% confidence limits). Two informative families with known crossovers between the A and B loci of the HLA region, moreover, indicate that the C4 locus is situated close to the B locus, as shown for the properdin factor B locus⁴.

A patient has been reported with no C4 in the serum, and

a study of the family suggested that the locus determining the level of C4 was closely linked to the HLA region¹³. Our findings suggest that the familial defect in C4 levels is due to a "silent" allele at the structural C4 locus.

The structural locus of properdin factor B, and loci determining the blood levels of C2 (ref. 14) and C8 (ref. 15) have been assigned previously to the HLA gene complex of chromosome 6. It is therefore not surprising that C4 is also encoded by a locus in this complex. It has been shown that the murine C4 locus is situated in the H-2 gene complex^{16,17}. The C3 locus in man is, however, not linked to HLA¹⁸.

In this context it is tempting to speculate that loci for different components of complement have appeared, during evolution, from one locus as results of local chromosomal events, for instance gene duplications and point mutations. Indeed it has been postulated that complement components have evolved from a single ancestral protein².

An interesting pattern emerges with respect to the role of this short segment of chromosome 6 in the immunobiology of vertebrates. It seems significant that many important factors in immune recognition, response and reaction are encoded by closely linked genes. The closeness at the chromosomal level may reflect functional integration of products of immune response genes, cell membrane allo-antigens and the complement system.

Note added in proof: Recently extended population material indicates that the frequency of the S gene may be appreciably lower than in the small sample presented here (~ 0.40).

Persistence of anti-immunoglobulin on the lymphocyte surface

It is well established that addition of anti-immunoglobulin (anti-Ig) to lymphocytes expressing Ig receptors produces "capping" followed by endocytosis or "sloughing" of the membrane Ig, the expression of which is greatly diminished until resynthesis occurs¹. Another property of anti-Ig in some species, notably the rabbit, is blastogenic activation of lymphocytes². It is known that for the activation of lymphocytes by plant mitogens, the mitogenic substance must persist on the cell membrane for several hours before irreversible activation of the cell occurs³. Similarly, the activation of rabbit lymphocytes by antiserum to allotypic Ig determinants is largely inhibited if the Ig expressing the target allotype is added within a few hours⁴. Thus there is an apparent conflict between these two phenomena, one of which centres around the rapid removal of membrane Ig, the other requiring the persistence of anti-Ig for longer periods. Accordingly, experiments were designed to test the degree of retention of anti-Ig and the re-expression of membrane Ig on the surface of lymphocytes treated with anti-Ig sera and retained in tissue culture for several days.

To study the fate of anti-allotype antibody on rabbit lymphocyte membranes *in vitro*, peripheral blood lymphocytes, homozygous for *b*-locus allotype determinants, were used. These lymphocytes were obtained from defibrinated blood by a gelatin sedimentation technique⁵. In all cases the cell suspensions were incubated at 37 °C for 1 h to reduce the level of cytophilically bound immunoglobulin. The lymphocytes were suspended in 1 ml of Eagle's MEM (Glasgow modification) supplemented with 10% heat inactivated FCS (MEM-F) to a cell concentration of 2×10^6 ml⁻¹. An appropriate volume (0.03 or 0.06 ml) of anti-allotype serum was added and the cells cultured for 24 h at 37 °C in 10% CO₂ in air. The cells were spun down, residual antiserum removed and the cells washed once in warm MEM-F, before reculturing in antibody-free MEM-F for 0, 1, 24 and 48 h. At each time period the cells were washed three times (finally in PBS) and fixed in 2% paraformaldehyde solution⁶. At the end of the experiment the fixed cells were tested for the presence of allotypic determinants characteristic of the membrane Ig and of the attached antibody by a mixed antiglobulin test (see Table 1). The allotypic determinants are known to survive the fixation procedure⁷ whereas antibody activity is destroyed. A rosette assay was chosen because it has the unique advantage of detecting surface Ig and excluding intracellular Ig.

The fate of the anti-allotype antibody and of the membrane Ig receptors is shown in Table 1. Anti-allotype antibody was readily detectable on lymphocyte membranes immediately after 24 h of incubation with antiserum and persisted on approximately the same number of cells for a further 2 d. A significant number of the cells bearing antibody appeared to be blast cells (see parentheses, Table 1). Little of this antibody seems to be taken up cytophilically on to Fc receptors, since similar results were obtained with an F(ab')₂ anti-allotype preparation. The rapid disappearance from the cell membrane of any Ig taken up from a normal b6 serum provides further evidence that the persistence of antibody is unlikely to be due to cytophilic binding (Table 2). However, as demonstrated using normal b6 serum, some cytophilic uptake of Ig does take place during the initial 24 h incubation, which appears to be greatly reduced 1 h after washing and effectively lost by 24 h in culture. This cytophilic uptake appears to be entirely by the Fc receptor since it did not occur with the F(ab')₂ preparation.

Immediately after the initial incubation the washed lymphocytes exhibited high levels of bound antibody, but

low levels of membrane Ig. After 24 h incubation most of the cells appeared to recover their membrane Ig which was maintained over a further 24 h in culture. The proportion of blast cells expressing membrane Ig was approximately the same as that on which the anti-allotype antibody was present.

The observation that complexes appear in the supernatants of cultured mouse lymphocytes after only 2 h of incubation with anti-Ig⁸ prompted an experiment to investigate the possible nonspecific uptake by lymphocytes of "shed" membrane Ig-anti-Ig complexes. For this experiment b9b9 lymphocytes were cultured in a supernate (presumed to contain b4 m-Ig-anti-b4 complexes) obtained after a 3-h incubation of b4 cells with antibody. The cells were fixed after 1, 18 and 42 h and rosetting performed. Less than 1% (3 in 500 cells) of the cells formed rosettes (and these seemed to be macrophages), indicating that cytophilic up-

Briefly the method for the mixed anti-globulin rosette assay⁸ was as follows. The fixed lymphocytes were mixed with a 1/50 dilution of anti-allotype serum (either anti-b4 or anti-b6) for 30 min at room temperature and washed. SRBC (5% suspension) sensitised with a 1/60 dilution of either b4 or b6 rabbit anti-SRBC Fab⁹ preparation for 30 mins at 37 °C and washed. Sensitised SRBC (0.06 ml of a 1% suspension) and the sensitised lymphocytes (0.06 ml of 2×10^4 ml⁻¹) were mixed and centrifuged at 200g for 2 min. The cell pellet was gently resuspended and Toluidine blue added (0.03 ml of a 0.2% solution). Lymphocytes binding four or more RBC were counted as positive and expressed in the table as the mean of duplicate tests. Appropriate specificity controls were included to test for the non-specific uptake of the sensitising antibody by paraformaldehyde fixed cells. No detectable uptake of an irrelevant antiserum (that is anti-b6 on b4b4 cells) was ever observed.

*All anti-allotype sera were used at optimum concentrations for lymphocyte stimulation. Lymphocytes of allotype b4b4 were used in experiment 1, 2 and 3, and of b6b6 in experiment 4.

†Anti-b5 showed cross reactivity with b4 Ig determinants.

Figures in parentheses denote the percentage of blast cells rosetting. (c) = caps; (r) = rings.

Rosetting was performed as described in the legend to Table 1. For experiment 2, approximately 12×10^6 lymphocytes (Ficoll-trisoli purified) were cultured at $6 \times 10^6 \text{ ml}^{-1}$ in MEM-F with 0.06 ml anti-b4 (b5b6) serum for 30 min at 4 °C. The cells were washed once in the cold, then cultured at 37 °C for 3 h in MEM-F. The supernates (0.6 ml) were then transferred to 2×10^6 b9b9 lymphocytes. After 1, 18 and 42 h at 37 °C, the cells were washed and fixed in paraformaldehyde and rosetting performed.

take of complexed antibody is not a significant source of cells expressing allotypic antibody determinants.

The experiments described demonstrate that some anti-allotype antibody persists for at least 48 h in culture after it has become fixed to the cell surface. This is in apparent conflict with the efficient "capping" of fluorescein-labelled antibody which has been shown to occur in this system⁸. There is also evidence in the experiments described here for the "capping" of antibody in the form of "capped rosettes". The explanation of these findings is that a part, perhaps a large part, of the antibody attached to membrane Ig is removed relatively rapidly by "capping" but the remainder persists for very long periods. Alternatively, antibody may persist as a result of binding to resynthesised membrane Ig. The fact that antibody persists on the surface well beyond 24 h is compatible with the induction of activation by anti-allotype serum. These results are consistent with findings for the fate of concanavalin A (con A) and phytohaemagglutinin (PHA) in lymphocyte cultures where about 70% of the surface-bound lectin has been shown to be rapidly removed, whereas the remainder is retained for longer periods¹⁰.

Lymphocytes do not seem to be unique in the mode of retention of surface-fixed substances. Other workers have demonstrated the persistence of KLH on membranes of macrophages¹¹, antigen-antibody complexes on dendritic cells¹² and DNP-D-GL copolymers on the surface of lymphocytes¹³ for long periods. ALG has also been shown to persist in micro patches on mouse lymphocytes for several hours¹⁴, a fact which is particularly interesting in view of the known lymphocyte-stimulating activity of these reagents¹⁵.

In conclusion, it has been demonstrated that antibody to membrane Ig persists on lymphocyte membranes for up to 3 d in culture. During this period membrane Ig is being resynthesised and blast transformation is taking place.

Immunodepression, high IgM levels and evasion of the immune response in murine trypanosomiasis

THERE is currently much interest in the devices evolved by parasites which enable them to evade the immune responses mounted by their hosts¹. One such device is the phenomenon of antigenic variation associated with the salivarian trypanosome infections of man and animals in Africa^{2,3}. Typically these infections show successive waves of blood parasitaemia. Each succeeding trypanosome population is characterised by a novel variant-specific glycoprotein antigen present in the parasite surface coat and not reactive with antibodies induced against preceding variants^{4,5}. Antigenic variation has a clear role in the evasion of host immunity and leads to chronic and usually fatal infections. More recently we have become aware of a possible additional component of the evasion mechanism, generalised immunodepression.

Depressed responses to heterologous antigens have been shown in experimental lymphomagenic virus infections^{6,7}, in malaria^{8,9}, and in trypanosome infections^{10,11}. Explanations of the immunodepression in trypanosomiasis are complicated by the concomitant high levels of IgM immunoglobulins, much of

Fig. 1 Altered responsiveness of *T. b. brucei*-infected mice to SRBC. Numbers of PFC in female BALB/c mice given 1×10^6 SRBC intraperitoneally various days before or after infection with *T. b. brucei* S42, 1,000 organisms given intraperitoneally. Each point is the arithmetic mean (± 1 s.e.) of the PFCs per spleen of five mice, and the points represent two overlapping series, series 1 (●), series 2 (○). PFC assayed by the slide method¹². a, Direct (IgM) PFC; b, indirect PFC developed using a rabbit anti-mouse specific IgG_{2a} antiserum titrated and used at a concentration such that the inhibitory constant (KI) and developing constant (KD) = 1.0 (ref. 25).

which appears not to be parasite specific¹²⁻¹⁵. Following a detailed study of the plaque-forming cell (PFC) response to sheep red blood cells (SRBC), and to other heterologous erythrocytes and antigens, in mice infected with *Trypanosoma brucei brucei*, we are able to suggest a possible link between high IgM levels and immunodepression. We further suggest that less than optimal anti-parasite responses result from the immunodepression which thus assists the parasite to evade host immunity.

Figure 1 summarises the data of a number of experiments in which the time intervals between infection and SRBC immunisation were varied. Experimental details are given in the figure and table legends. When SRBC were injected 1-4 d after infection there was enhanced responsiveness, with both IgM and IgG-PFC being 2-3 times those of the uninfected immunised controls. But when SRBC were given 5 or more days after infection, the PFC responses were diminished; at 7 d both IgM and IgG PFC were equal only to background values. This profound depression persisted for the remainder of the infection. Clearly the effect of the infection on the PFC response depends on the temporal relationship between the day of infection and the antigen presentation; responses early in infection may be enhanced whereas later responses are depressed. These findings are broadly similar to the enhancement or suppression of haemolysin production in mice treated with bacterial lipopolysaccharide (LPS)¹⁶. The response was enhanced if LPS was given at the same time or shortly after SRBC, but was largely inhibited if LPS was given 1 or 2 d before the antigen.

We also observed a progressive increase in "background" IgM PFC to SRBC in infected, non-immunised mice. The time course of this background increase is shown in Fig. 2 in relation to the blood parasitaemia. By days 3-4 of infection a pronounced rise is seen which reaches plateau levels by about day 9. Numerous observations indicate that the plateau level of IgM PFC is usually 20-30 times that of uninfected control mice. We next investigated the background PFC of infected mice to two other heterologous erythrocytes, and to three other antigens coated on to SRBCs (Table 1). The values in Table 1 are mainly expressed as PFC per spleen because our interest centres on the total Ig production of the animal. As, however, splenomegaly develops in murine trypanosomiasis, we also express PFC per 10⁶ spleen cells in selected instances (Table 1b). In all cases, background IgM PFC were significantly increased,

Fig. 2 Rise in SRBC background IgM PFC in *T. b. brucei*-infected mice in relation to blood parasitaemia. Male BALB/c mice were infected with 1,000 *T. b. brucei* S42 intraperitoneally. Each point is the arithmetic mean (± 1 s.e.) of the PFC per spleen of four or five mice. The points represent direct (IgM) PFC in two overlapping series, series 1 (\bullet), series 2 (\circ), all groups within a series being assayed on the same day. Each point on the parasitaemia curve (\blacktriangle — \blacktriangle) represents the mean blood parasitaemia count of 10 mice.

particularly so with the TNP hapten. Because of the number and variety of antigens tested, it seems not unreasonable to assume that the background IgM responses to all antigens recognisable by B cells are increased in trypanosome-infected mice, and that the trypanosome infection therefore induces polyclonal B-cell activation. Indeed, Coutinho and Moller¹⁷ have argued that a marked increase in background IgM PFC to a highly hapten-substituted target cell, such as our TNP-coated SRBCs, is in itself a good measure of polyclonal B-cell activation. They state that such rises, although not specific, reflect increases in the background responses to a variety of cross-reacting determinants. Again a parallel may be drawn between the polyclonal activation of trypanosome infections and that produced by LPS¹⁸. The secreted polyclonal products would then account for the increased Ig levels seen in the infection; by day 14 serum IgM levels had increased 8-16-fold

Table 1 Increase in number of background PFC to a variety of antigens in mice infected with *T. b. brucei*

Each PFC is the arithmetic mean (± 1 s.e.) of 4-5 mice. Antigens: SRBC, HRBC, DRBC; sheep, horse and donkey erythrocytes: SIII; SRBCs coated with type III pneumococcal capsular polysaccharide using broth culture supernatant¹⁹; CGG; SRBC coated with chicken gamma globulin by incubating equal volumes of 10% SRBC and chicken anti-SRBC antiserum ($\frac{1}{4}$ minimum agglutinating titre) at 37 °C for 30 min. and washing three times: TNP; trinitrophenol determinant coated on to SRBC using TNBS²⁰. The values for SIII, CGG and TNP were calculated according to the formula: PFC.Ag = PFC.Ag SRBC - (PFC.SRBC \times CF). The correction factor (CF) is a measure of the efficiency of lysis of antigen-coated SRBC by anti-SRBC.PFC, and thus reflects the degree of antigen coating. For example in the first series, CF values for SIII, CGG and TNP were 0.46, 0.48 and 0.63. These ratios were established on the day of assay using the same batches of antigen-coated SRBC as in the experimental groups, and were calculated from the geometric means of 10 duplicates using log(x + 1) transformation. The assays were performed on the pooled spleen suspensions from three BALB/c mice given 1×10^6 SRBC intraperitoneally 5 d previously.

and IgG₂ had increased four- to fivefold in these *T. b. brucei*-infected mice (Hudson and Byner, unpublished observations). Table 1 does show increases in background IgG PFC to sheep, horse and donkey RBC, but these increases vary widely from experiment to experiment and never approach the increases seen in background IgM PFC. Polyclonal B-cell activation has previously been suggested to occur in malaria and trypanosomiasis^{19,20}, but hitherto mitogenic activity of these parasites has only been demonstrated *in vitro*^{21,22}.

We believe that the polyclonal activation of B cells in the presence of a continuous trypanosome infection is likely to result in a progressive depletion of antigen-reactive B lymphocytes as these are activated to change into secretor cells, perhaps with little accompanying proliferation. In this way the immunodepression occurring later in the infection may be explained by the depletion of B cells capable of recognising the introduced antigen. Diamantstein and his colleagues²³ have shown suppression of primary responses *in vivo* to SRBC by a number of B-cell mitogens. They believe that when B cells react with a mitogen in the absence of a particular antigen, they temporarily lose their capacity to respond to that antigen. The longer term immunodepression associated with murine trypanosomiasis might then result from the continuous exposure of B cells to trypanosomes and their products.

Finally, if both activation and immunodepression are polyclonal it would be expected that the antibody responses to later-appearing trypanosome antigenic variants would also be impaired. The pattern of infection with S42 *T. b. brucei* (Fig. 2) lends some support to this view. The infection shows waves of parasitaemia which have been shown to be antigenically distinct (K.M.H., C.B., and A. E. R. Taylor, unpublished). The first wave subsides around days 8–9, due to the production of variant specific antibodies. The second major wave, in spite of some minor fluctuations, never subsides to the same degree as the first wave but continues to rise until the death of the mouse. This may perhaps indicate that the production of variant specific antibodies is depressed at this stage of the infection. We are at present attempting to obtain direct evidence on this point and are also investigating a series of more chronic infections. Meanwhile it is a reasonable working hypothesis that high IgM levels, immunodepression of responses to heterologous antigens, and the less than fully effective anti-trypanosome responses are linked, and are brought about by the trypanosomes either directly or indirectly activating the host B cells polyclonally.

We thank Jean Macfarlan for technical assistance; Drs John Humphrey and David Dresser for gifts of SIII-containing broth culture supernatant and chicken anti-SRBC antiserum respectively; and Dr W. R. Allen for supplying the HRBC and DRBC. This work was supported by a grant from the Trypanosomiasis Advisory Panel of the Ministry of Overseas Development.

Absence of intestinal mast cell response in congenitally athymic mice during *Trichinella spiralis* infection

DURING the intestinal phase of nematode infections in laboratory rodents a variety of cell types is found in the gut mucosa, including mast cells and globule leukocytes^{1–4}. After stimulation by the nematodes present either in the intestinal lumen or penetrated into the gut mucosa, the number of intestinal mast cells increases^{1–4}. Next, mast cells invade the epithelial lining of the villi, discharge secretory products, including histamine, and change into the intra-epithelial globule leukocytes^{1–4}. Release of mast cell secretory products is mediated by IgE antibody⁵. No conclusive evidence has as yet been presented, that the secretory products have a role in the expulsion of the worms.

In earlier studies⁴ the thymus dependence of both intestinal mast cell production and globule leukocyte formation was studied in *Trichinella spiralis* infected rats with and without anti-thymocyte serum (ATS) treatment. ATS treatment did not influence mast cell production, but had an adverse effect on mast cell degranulation which was attributed to a possible decrease in IgE level in the ATS-treated rats. Since in ATS-treated animals a residual pool of T cells can be expected as well as an intact thymus, we repeated these experiments in congenitally athymic (nude) mice and their heterozygous thymus-bearing (+/nu) littermates. In +/nu mice *T. spiralis* adult worms are expelled from the intestinal tract within 10 d after infection, whereas in nude (nu/nu) mice worms are present until at least 50 d after infection^{7,8}, indicating T-cell dependence of host protection against a *T. spiralis* infection.

Male SPF B10LP nude (nu/nu) mice, 6 weeks of age, were obtained from the Central Laboratory for the Breeding of Laboratory Animals TNO, Zeist, The Netherlands, where the mice were maintained by conventional back crossing with strain B10LP. Comparisons were made with age-matched mice heterozygous for the nude gene (+/nu). At an age of 8 weeks the mice were orally infected with 100 *T. spiralis* larvae each, using a syringe. Animals were autopsied from 3 to 16 d after infection. The presence of intestinal mast cells and globule leukocytes was studied in a 10-cm portion of the proximal jejunum with a swiss-roll technique⁹. Tissues were fixed in a special fixative, adopted after preliminary studies, since intestinal mast cells differ in their staining properties from tissue mast cells elsewhere in the body and the fixative proposed for rat intestinal mast cells¹⁰ proved inadequate. The fixative was composed of a mixture of 0.8% formalin buffered with phosphate-buffered

Fig. 1 Mean number of intestinal mast cells and globule leukocytes in a 10-cm portion of the proximal jejunum (expressed per 100 "villus crypt" units) in groups of 4-5 $+/\nu$ mice infected orally with 100 *T. spiralis* larvae each. Statistical analysis (Student's *t* test). Mast cells: day 3 against day 0, $P < 0.001$; day 7 against day 0, $P < 0.01$; other days after infection against day 0, not significant. Globule leukocytes: day 3 against day 0, not significant; day 7 against day 0, $P < 0.001$; day 10 against day 0, $P < 0.001$; day 13 against day 0, $P < 0.01$; day 16 against day 0, $P < 0.001$. \circ , Mast cells; \bullet , globule leukocytes.

saline (0.01 M; pH 7.2) at neutral pH and 4% acetic acid. After overnight fixation at 45 °C tissues were dehydrated and embedded in paraplast according to conventional procedures. Sections (5 μ m thick) were prepared and stained with toluidine blue for 20 min at room temperature. Toluidine blue (0.5%) was dissolved in 20% ethanol. After filtration the solution was used for staining. After staining the sections were washed, dehydrated and mounted with a conventional mounting medium.

Cells present in the intestinal mucosa were counted in the whole swiss-roll and their number expressed per 100 "villus-crypt" units. A "villus-crypt" unit represents a portion of gut mucosa, lying between two gland crypts and the lamina propria of the villus above¹¹. Non-*T. spiralis*-infected animals served as controls (day 0 in Figs 1 and 2).

The results of the mast cell and globule leukocyte counts in the $+/\nu$ mice are shown in Fig. 1, the corresponding counts for the ν/ν mice in Fig. 2.

In $+/\nu$ mice, the number of intestinal mast cells decreased at day 3 after infection and showed a rise at day 7, after which a gradual decline was observed. The number of globule leukocytes increased noticeably from day 7 to day 10 after infection; at days 13 and 16 a decline was seen. In ν/ν mice, mast cells and globule leukocytes were present at day 0, although the number was much lower

than that found in $+/\nu$ mice. During the course of the infection no change in number of either cell type was observed.

The intestinal mast cell response in $+/\nu$ mice corresponds with that described for rats infected with *T. spiralis*⁴ or *Nippostrongylus brasiliensis*⁵. The initial decrease in number of mast cells is attributed to toxic metabolites secreted by the parasite¹². The subsequent increase in number of intestinal mast cells has been tentatively attributed to proliferation of precursor cells of lymphoid origin¹³. The increase of globule leukocytes is in keeping with the intestinal mast cell degranulation theory.

The fact that in non-infected ν/ν mice only occasional intestinal mast cells and globule leukocytes were found is in contrast to the abundance of tissue mast cells elsewhere in the body of these athymic mice, as observed by us and others¹⁴. Furthermore, the continuous presence of the parasites⁸ did not cause an increase in either intestinal mast cell or globule leukocyte numbers.

An explanation for these findings could possibly be found in the as yet unknown origin of the mast cell. Various authors have suggested that mast cell formation may be

Fig. 2 Mean number of intestinal mast cells and globule leukocytes in a 10-cm portion of the proximal jejunum (expressed per 100 "villus crypt" units) in groups of 4-5 ν/ν mice infected orally with 100 *T. spiralis* larvae each. Statistical analysis (Student's *t* test). Mast cells: all days after infection against day 0, not significant. Globule leukocytes: all days after infection against day 0, not significant. \circ , Mast cells; \bullet , globule leukocytes.

thymus dependent¹⁵⁻¹⁸. Burnet¹⁶ speculated that mast cells and basophil leukocytes, or some subpopulation of such cells, are post-mitotic derivatives of thymus-derived (T) lymphocytes. On the other hand, thymic hormones can possibly also have a role in the differentiation of mast cells¹⁹.

To examine this possibility we performed reconstitution experiments. Thymus transplants of 6-week-old male donor B10LP $+/\nu$ mice were grafted subcutaneously in a group of 9 male B10LP ν/ν mice, 6 weeks of age (two thymuses per recipient). The animals were autopsied at an age of 12 weeks. A group of 10 male B10LP $+/\nu$ mice and a group of seven non-reconstituted male B10LP ν/ν mice, served as controls. Animals of both groups were 12 weeks old. The number of intestinal mast cells was counted in a 10-cm portion of the jejunum. The number of intestinal mast cells in the reconstituted mice was comparable (20-30 cells per 100 "villus crypt" units) to the number of cells counted in the jejunum of the $+/\nu$ mice, whereas none were seen in the non-reconstituted ν/ν mice which is consistent with thymus dependence of the formation of intestinal mast cells.

In all published studies results are based on tissue mast cells. In the athymic mouse tissue (non-intestinal) mast cells seem to be as abundant as in its thymus-bearing littermates. This is not consistent with the idea that the tissue mast cell is an end-stage of the T lymphocyte. In the formation of intestinal mast cells, however, the thymus clearly has an essential role.

The conclusions of the present experiments are therefore:

(1) no intestinal mast cell response accompanies a *T. spiralis*

infection in congenitally athymic (nude) mice, and (2) intestinal mast cells represent a separate population of mast cells, which is "T dependent".

Virus-like particles and GB agent hepatitis

ALTHOUGH the MS-1¹ and CR326² strains of human hepatitis A virus have been well characterised morphologically and shown to be indistinguishable, controversy has plagued characterisation of the GB agent of hepatitis³. Presumably derived from a surgeon with acute hepatitis, the GB agent has been transmitted serially in marmoset monkeys³ but has been shown to be unrelated serologically to any known human hepatitis virus⁴. Recently, Almeida *et al.*⁵ reported the detection after prolonged search of 20-22-nm particles aggregated by endogenous antibody in a pool of marmoset sera (pool H205, GB pass 11) known to contain the GB agent. These antibody-coated particles resembled parvoviruses morphologically, appeared in "empty", "full", and fragmented crescent-shaped forms, and were undetectable in normal marmoset serum. On the basis of previous filtration data from Deinhardt *et al.*⁶ which suggest that the GB agent is approximately 20 nm in diameter and the previous finding by others that anti-complementary activity—thought to represent the presence of circulating antigen-antibody complexes—occurs during acute viral hepatitis, Almeida *et al.* suggested that the virus-like particle they have detected is the GB agent⁵.

Using a different approach in an attempt to detect the GB agent, we examined by immune electron microscopy homogenates of liver obtained during the height of acute GB infection from individual *Saguinus mystax* and *S. nigricollis* marmosets that had been inoculated with GB agent pools provided by Deinhardt. The same approach had been used successfully by Provost *et al.*² to identify the CR326 strain of human hepatitis A virus in marmoset liver. The homogenate of one liver obtained from a *S. mystax* marmoset (No. 49) (inoculated with the GB H205 pool) when serum isocitrate dehydrogenase activity was 4,680 IU (>4 times normal) was clarified and banded in a caesium chloride (CsCl) gradient (1.1-1.6 g cm⁻³). Each gradient fraction was incubated with convalescent serum from a marmoset (*S. mystax* No. 50) convalescent from hepatitis induced by the H205 pool of GB agent and examined by immune electron microscopy¹. As shown in the figure, aggregates of approximately 34-36-nm diameter particles resembling viruses with icosahedral symmetry were

detected at a buoyant density of 1.4 g cm⁻³. Both "empty" and "full" particles were observed, but empty particles were more abundant. In limited serological studies performed under code, when these particles were incubated with pre-inoculation serum from marmoset No. 50, antibody-coated aggregates were also detected, but no antibody was seen when the particle-containing gradient fraction was incubated with saline. In addition, no antibody to this particle could be detected in the convalescent serum of the surgeon from whom the GB agent was isolated.

The diameter of these particles corresponds closely to the size deduced by Parks and Melnick⁷ for the GB agent from their filtration data; however, the failure of this virus-like antigen to distinguish under code between pre-inoculation and convalescent GB serum raised questions about its relationship to the GB agent. To pursue these findings, we examined CsCl gradients from homogenates of livers obtained from five *S. mystax* marmosets with hepatitis A virus infection, from one normal *S. mystax* marmoset, from one *S. mystax* marmoset convalescent from GB infection, and from two *S. nigricollis* marmosets acutely infected with a different GB agent pool (H118).

Virus-like particles indistinguishable from those seen in

Fig. 1 Examples of aggregates of antibody-coated 34-36-nm particles detected in a liver homogenate from *S. mystax* marmoset No. 49 acutely infected with the GB agent. The liver was frozen at -70 °C immediately after the death of the marmoset. A 20% homogenate of the liver was made in distilled water after mincing with fine scissors and grinding with mortar and pestle. After the homogenate was clarified to remove large debris (1,000g for 1 h at 4 °C), 4 ml of supernatant fluid was layered on a 9-ml discontinuous preformed 6-step CsCl gradient (1.1-1.6 g cm⁻³) prepared in a cellulose nitrate tube for a Beckman SW 40 rotor (Beckman Instruments). The gradient was centrifuged in a Beckman L2-65B ultracentrifuge for 18 h at 35,000 r.p.m. (4 °C) and collected from the bottom in fractions of approximately 1 ml each. Each fraction was incubated with convalescent serum from *S. mystax* marmoset No. 50, which was convalescent from GB infection, and examined by immune electron microscopy as described¹. (Original magnification 194,400. 2% phosphotungstic acid stain.)

the first GB-infected liver were found in the two livers from marmosets acutely infected with the GB agent but in neither of the livers from the normal or GB-convalescent marmosets nor in livers from marmosets with hepatitis A virus infection (Table 1). Unfortunately, the quantity of antigenic material extracted was insufficient to allow more extensive serological evaluation, and the particles seemed to be relatively unstable after extraction.

Correlation of the size of these particles with size determinations performed by filtration of the GB agent⁷ and the specificity of their detection in GB-infected livers suggest that they may be the GB agent. If this is true, the presence of antibody in preinoculation serum is difficult to explain, unless (1) GB-related illness represents reinfection with a virus serologically related to a previously experienced virus, or (2) the GB agent is a latent virus of marmosets to which antibody is produced but which can become reactivated during periods of stress, like herpesviruses of man. Such an hypothesis agrees with the isolation of a GB-like agent from uninfected marmosets, as reported by Parks and Melnick⁸. Indeed, even if the 20–22-nm particle described by Almeida *et al.* is the GB agent, the fact that antibody to it exists in the infectious inoculum suggests an unusual immunological relationship between virus and host.

Table 1 Virus-like particles in the livers of marmosets

Category of marmoset	No. with 34–36-nm particles in liver/No. tested
GB agent-infected	
Acute	3/3
Convalescent	0/1
Hepatitis A virus-infected (acute)	0/5*
Normal	0/1

*27-nm hepatitis A antigen particles were detected in three of these.

Another discrepancy between earlier studies of the GB agent and both Almeida's and this report concerns the buoyant density of the particles. Original banding studies by Holmes *et al.*⁴ revealed a peak infectivity at a density of 1.18–1.23 g cm⁻³ for both the GB agent and the MS-1 hepatitis A virus strain. The particles identified by us have a density of approximately 1.4 g cm⁻³, and if Almeida's particles are parvoviruses or even parvovirus-like, a density of 1.4 g cm⁻³ or greater is to be anticipated. Although hepatitis A virus is known to be infectious at densities ranging from 1.15 to 1.41 g cm⁻³, the main density is thought to be approximately 1.34 g cm⁻³ (ref. 2); infectivity at densities <1.2 g cm⁻³ probably represents virions bound to lipid-containing contaminants. Conceivably the original biophysical data of Holmes *et al.* for both the GB agent and hepatitis A virus were derived with such lipid-associated material and do not represent the true density suggested by more recent studies.

If indeed, as Almeida's study suggests, the GB agent is parvovirus-like, the lipid solvent sensitivity and the instability of the GB agent reported by both Deinhardt's and Melnick's groups^{7,9} are in contrast to the marked heat stability and resistance to lipid solvents that characterise the parvoviruses¹⁰.

Clearly, data to support the candidacy of the 20–22-nm particle or the 34–36-nm particle for the elusive GB agent are incomplete. Additional studies are required to determine whether (1) either of these particles is related to GB infection, (2) an as yet unidentified particle is the GB agent, (3) GB is of human or marmoset origin, and (4) the parvovirus-like particles are related to those recently detected in human serum¹¹. Morphologically similar 22-nm particles are ubiquitous in faeces, and, although once

thought related to viral gastroenteritis, are no longer considered to be associated with any known human disease¹². Moreover, since Almeida *et al.* looked at a pool of sera, antibody from one serum might have aggregated virus in another. It will therefore be necessary to examine individual marmoset sera obtained during GB infection to establish the presence of circulating immune complexes. Until a virus-like particle is identified which can be serologically related to GB illness or can be aetiologically associated with infection by other means, morphology of the GB agent will remain a matter of conjecture.

Avian cell transformation and the expression of avian sarcoma virus-specific tumour antigens

MALIGNANT cell transformation is often accompanied by the appearance of new cell-surface antigens^{1–3} of four classifications (defined in ref. 3): (1) embryonic antigens (EA) that are also present on normal embryonic cells; (2) differentiation antigens (DA) so called because they are also expressed on certain normal syngeneic or allogeneic cells; (3) virus structural antigens (VSA) inserted in the surface membrane of infected cells which may or may not be transformed, and (4) tumour-specific transplantation antigens (TSTA), antigens associated with tumour rejection.

Here we ask the questions first, does transformation of avian cells by agents other than avian sarcoma viruses (ASV) induce a tumour-specific surface antigen (TSSA) hitherto recognised as avian oncornavirus specific; and second, does the additional genetic information supplied by a superinfecting avian leukosis virus (ALV) or ASV lead to TSSA expression? Our experiments suggest that transformation by ASV is necessary for the induction of this antigen.

The operationally defined TSTA have received widespread attention in the past. Appropriately immunised animals will reject a subsequent challenge by viable syngeneic tumour cells because of their anti-TSTA immunity.

Fig. 1 Specific absorption of anti-TSSA immunoglobulins G to quail cells infected by avian leukosis sarcoma viruses and/or Kirsten sarcoma or simian sarcoma associated viruses. Cells growing in 16-mm Linbro 96 CV-TC tissue culture plates were counted and fixed at subconfluency (about 10^5 cells per culture) and incubated in duplicates with exactly equal amounts (16 μ g or dilutions thereof) of 125 I-IgG from normal or anti-TSSA (No. 62) chicken sera as described previously^{8,9}. Incubation was stopped by aspiration of the IgG dilutions and 4 washes of 5 min each with PBS. The absorbed antibodies were eluted from the cells with pH 1.2 KCl-HCl buffer and their radioactivity was assessed in a well-type scintillation counter. The number of specifically absorbed antibodies was calculated from the specific radioactivity of the anti-TSSA IgG-preparations minus background absorption of normal IgG (usually less than 20%). Quail cells were infected by the following virus strains: \times , Prague A or B77-C avian sarcoma virus strains; \square , Rous (-) sarcoma virus; \circ , 23.16 = a Rous(-) transformed quail cell line; \triangle , KiSV(SSAV) plus Prague A-ASV. Uninfected cells (controls) or cells infected by the following virus strains showed no specific absorption: RAV-1, RAV-49, KiSV (SSAV), KiSV(SSAV) + RAV-1, KiSV(SSAV) + RAV-49. All data are taken from one characteristic experiment.

Tumours induced both by chemicals and by viruses express TSTA of widely varying antigenicity and immunogenicity. Whereas in the case of chemical tumours TSTA by necessity must be cell coded, their origin in virus tumours is not known. Virus-induced TSTA, which are not incorporated into virus particles, are virus-group specific. Only virus strains belonging to the same tumour virus group will induce cross-reacting TSTAs.

In the avian oncornavirus system, a TSSA has been detected which seems invariably to be expressed on the cells of various species transformed by avian leukosis

sarcoma virus strains (reviewed in ref. 4). It is a rejection-inducing transplantation-type neoantigen (TSTA). Its origin is also unknown. It may be a direct viral gene product or appear as a consequence of virus-activated cellular genes. Chicken embryo fibroblasts infected but not transformed by avian leukosis viruses *in vitro* do not express TSSA, but chickens infected with leukosis viruses may develop immunity to tumour cell challenge, indicating that *in vivo* these viruses can elicit the antigen⁵⁻⁷. The expression of the genes coding for TSSA may in turn depend on the cell possessing a transformed phenotype and ALV may only find the appropriate target cells to form this interaction *in vivo*.

Avian cells are generally refractory to transformation by viruses other than the avian oncornaviruses. However, xenotropic oncornaviruses from mice and other mammals are infectious for avian cells. In this respect, the simian sarcoma associated virus (SSAV) is a xenotropic virus with this capability and can be used to construct a pseudotype with the Kirsten strain of murine sarcoma virus KiSV (SSAV) which will readily infect and transform Japanese quail cells. (This virus was provided by Dr R Weiss.)

Outbred Japanese quail cells between the second and tenth passage served as targets for virus infection and transformation. Only cells from a single embryo were used in any one experiment and the normal or anti-TSSA

Table 2 Uptake of radioactive 3 H-2-deoxyglucose by virus-infected quail cells

Virus	Morphology	Uptake $\times 10^{-6}$ cells (c.p.m.)	Ratio*
Uninfected	Normal	7,800	—

*The agar suspension technique was performed as described in reference¹¹.

†ALV: avian leukosis virus strains used: RAV-1, RAV-49.

‡ASV: avian sarcoma virus strains used: Prague-A, B77-C.

IgG preparations were always exhaustively absorbed with normal cells before their use in the anti-globulin absorption technique^{8,9}. In this test the difference in absorption of radioactively labelled normal and anti-TSSA IgG molecules to mildly fixed target cells is taken as measurement for the amount of TSSA-expression (see legend to Fig. 1). RAV-1 and RAV-49 are avian leukosis virus strains which infect but do not transform quail cells. In contrast, the avian sarcoma virus strains Prague-A and B77-C both infect and transform quail cells as efficiently as KiSV(SSAV). The replication-defective Rous(-) strain of ASV was included in these studies for direct comparison with KiSV, which is also replication-defective in solitary infections without helper viruses like SSAV.

Since superinfection with leukosis viruses does not lead to phenotypic alterations of the infected cells, successful ALV infection of normal or KiSV(SSAV) infected quail cells had to be demonstrated by interference tests¹⁰. Dilutions of up to 10^{-7} of 1 ml of supernatant medium from each of the RAV-1 or RAV-49 infected cultures were used to infect normal quail cells and were able to prevent subsequent superinfection by focus-forming Prague-A or B77-C sarcoma virus strains, respectively.

‡For details see Fig. 1.

This high interfering titre indicated that most if not all cells had been successfully infected by ALV-strains.

Morphological transformation of quail cell cultures occurred within two passages after infection by the avian or murine sarcoma virus strains. First it had to be shown by criteria other than morphology that these cells were indeed transformed. Table 1 shows that only the sarcoma virus transformed quail fibroblasts possessed the ability to grow and form colonies in semi-solid agar¹¹. Superinfection of KiSV(SSAV) transformed cells by ALV or ASV did not alter their potential for colony formation. In contrast, uninfected or ALV-infected non-transformed cells showed no ability to grow in agar.

Another characteristic parameter of transformed cells is their enhanced rate of uptake of certain sugars^{12,13}. Again only the quail fibroblasts transformed by sarcoma virus strains expressed this property (Table 2).

Having thus defined the normal or transformed phenotype of the virus-infected cells, the specific absorption of anti-TSSA immunoglobulins to the cell surfaces was tested. As can be seen in Fig. 1, only fibroblasts infected or superinfected by avian sarcoma viruses absorbed anti-TSSA antibodies. Cells transformed by the murine sarcoma virus strain KiSV did not express TSSA even when superinfected with ALV. However, superinfection of KiSV-(SSAV) transformed quail cells with ASV strains led to TSSA-induction. All TSSA-positive cell types expressed a similar amount of TSSA, whereas the TSSA-negative cells showed practically no specific absorption.

Table 3 gives a summary of the phenotypic properties of the virus-infected cells. The encircled results point to a clear difference in TSSA expression in the cells tested.

Infection and transformation of fibroblasts by ASV leads to the induction of the avian TSSA; infection by ALV does not (reviewed in refs 2–4, and 14). TSSA-expression seems to be a consequence of ASV-transformation. All ASV-transformed cells of a variety of avian or mammalian species expressed TSSA, which is thus not only a marker for the oncogenicity of ASV, but can also be used in its partially purified form for successful anti-tumour immunisation (H. Bauer and M. Hayami, personal communication). Here we have demonstrated that ALV infection, even in a cell already possessing a transformed phenotype, does not lead to the expression of TSSA.

The sole important genetic difference in the genomes of ASV and ALV is the sarc-gene of ASV, which is not part of the ALV genome and seems to be responsible for fibroblast transformation^{15–17}. We are aware of no experimental evidence contradicting the notion that expression of the sarc-gene inevitably leads to the expression of TSSA in the plasma membrane of fibroblasts. It can, but does not necessarily mean that TSSA is coded for by the sarc-gene and thus represents a primary transforming protein. It is also possible that the primary transforming protein coded for by the sarc-gene induces TSSA synthesis by cellular genes. To distinguish between the

latter two possibilities, *in vitro* protein synthesis experiments have been initiated to attempt the transcription of the protein portion of TSSA from ASV-RNA *in vitro*.

Immunological identification of two adenovirus 2-induced early proteins possibly involved in cell transformation

HUMAN adenovirus 2 (Ad2), a DNA tumour virus that replicates in the nucleus of permissive human cells^{1,2}, transforms non-permissive or semipermissive cultured rodent cells, but does not induce tumours in newborn hamsters (oncogenic group C). The constant functioning of protein product(s) from Ad2 'transforming gene(s)' is probably responsible for the transformed phenotype, although this has not been proved. Identification and functional characterisation of 'transforming protein(s)' are important for the understanding of cell transformation and growth control. We describe here immunoprecipitation studies made with antisera against presumptive Ad2 'transforming protein(s)', that identify two candidate transforming proteins of 53,000 (53k) and 15k daltons.

Ad2-transformed cells retain viral DNA and synthesise viral RNA sequences that are a subset of those produced during 'early' stages of productive infection, before initiation of viral DNA replication³. All Ad2-transformed cells examined contain the left 14% of the Ad2 genome, that is map positions (MP) 0–0.14 (ref. 4). These cells express mRNA from Ad2 DNA about MP 0.02 to 0.10 assuming a continuous transcript, that are also expressed

early⁵. Some Ad2-transformed cells contain and express other sections of the viral genome, but none contain the entire genome^{4,5}. Cultured rat cells are transformed by transfection with G fragment (MP 0-0.075) generated by cleavage of Ad2 or Ad5 (oncogenic group C) DNA with restriction endonuclease *HindIII*, and digestion of more than 1% of DNA by exonuclease III + *S*₁ nuclease results in loss of transforming activity⁶. These studies indicate that information for cell transformation lies somewhere between Ad2 MP 0.01 and 0.075, and is expressed early after infection.

To identify Ad2 transforming protein(s) we prepared antisera against viral proteins expressed in Ad2-transformed rat cells by injecting sonicated F17 cells into rats. Cell line F17 (P. H. Gallimore) contains only the left 14% of the Ad2 genome⁴, and thus viral proteins should include and be mainly transforming proteins. We also used antisera from hamsters immunised with extracts of tumours induced in hamsters by Ad2-SV40 and Ad1-SV40 (Ad1 is in oncogenic group C) hybrid viruses (antisera were obtained from Dr R. Gilden⁷). The Ad2 DNA sequences present in the Ad1- and Ad2-SV40-induced tumours have not been determined. IgGs from F17 and hamster antisera were used to immunoprecipitate ³⁵S-labelled polypeptides produced in human KB cells early after productive infection. Polypeptides were identified by polyacrylamide slab gel electrophoresis and

autoradiography. Injection of Ad2-transformed rat or hamster cell extracts into rats or hamsters, respectively, should minimise induction of antibodies to rat or hamster proteins, and therefore decrease the danger of immunoprecipitation of human proteins from Ad2-infected KB cells by possible cross-reacting antibodies to rat or hamster proteins. Accordingly, proteins specifically immunoprecipitated by F17, Ad1-, or Ad2-SV40 IgG from Ad2-infected KB cell extracts should be virus specific.

In studies of Ad2 early proteins cells are treated with arabinosyl cytosine (ara C) 4h after infection and labelled in the presence of ara C; this prevents viral DNA replication and consequently the onset of late stages of infection, so that only early viral polypeptides are labelled. Two polypeptides (75k DNA binding protein, 21k) are in infected cell extracts (Fig. 1b), that are absent from uninfected cells (Fig. 1a). Treatment of cells with cycloheximide before labelling enhances viral protein synthesis relative to host⁸. In this gel 5 Ad2 induced early proteins are visible after cycloheximide pretreatment (Fig. 1d): 75k, 21k, 19k, 15k, and 11k (a 11.5k polypeptide forms part of the 11k band). Using longer gels (27cm) with higher resolution we have observed as many as 13 Ad2-induced early polypeptides, but do not know whether each is a product of a unique viral gene.

Immunoprecipitation studies using F17 IgG are shown in Fig. 1, e-l. Cells were not pretreated with cycloheximide, and were

Fig. 1 Autoradiogram of sodium lauryl sulphate-polyacrylamide slab gel showing electrophoretic separation of ³⁵S-polypeptides induced in human KB cells by Ad2 early after infection, and immunoprecipitated by rat antiserum against extracts of Ad2-transformed F17 rat cells. KB cells suspended in Eagle's MEM at 6×10^6 cells per ml were infected with 100 plaque-forming units per cell of Ad2^{9,10}. A second culture of KB cells was treated in a similar manner in this and subsequent steps, but without addition of virus, to serve as a mock-infected control. After 1h adsorption cells were diluted to 3×10^5 cells per ml with MEM containing 5% horse serum and 10 mM HEPES, pH 7.2. Four hours after infection arabinosyl cytosine (ara C) was added to $20 \mu\text{g ml}^{-1}$. At 6h after infection cells were resuspended at 9×10^5 cells per ml in methionine-free MEM containing 5% horse serum, 10 mM HEPES, pH 7.2, and ara C ($20 \mu\text{g ml}^{-1}$), and labelled for 6h with ³⁵S-methionine ($25 \mu\text{Ci ml}^{-1}$, 273 Ci mmol⁻¹). After labelling, cells were washed twice by centrifugation with ice-cold phosphate-buffered saline (PBS), suspended at 18×10^6 cells per ml in reticulocyte standard buffer, allowed to swell for 15 min, and disrupted by 30 strokes of a tight-fitting Dounce homogeniser. Nuclei were collected by centrifugation and the perinuclear membrane was removed by the 'double-detergent' washing procedure¹⁴ using Tween 40 and sodium deoxycholate. Nuclei were suspended in radioimmune precipitation (RIPA) buffer¹⁵, sonicated for 3 min, incubated at 20°C for 150 min, and clarified by centrifugation (4°C) at 31,000g for 20 min. RIPA buffer is 10 mM sodium phosphate, pH 7.2, 150 mM NaCl, 1%, Triton X-100, 1%, sodium deoxycholate and 0.1% sodium lauryl sulphate. The postnuclear cytoplasm was mixed with 0.1 volume of $10 \times$ RIPA buffer, incubated at 20°C for 15 min, and clarified as described for nucleoplasm. F17 cells for immunisation were grown in Ca^{2+} -free MEM supplemented with 10% foetal calf serum. Before each injection, cells were collected by scraping with a rubber policeman, washed three times in PBS, and sonicated for 3 min. A sonicated 10% cell suspension in PBS was emulsified with 1 volume of Freund's complete adjuvant and 0.5 ml of emulsion was injected intraperitoneally into each rat. Eight injections were performed at weekly intervals and rats were exsanguinated 9d after the last injection. Immune sera from four Sprague-Dawley and three Wistar rats were pooled. IgG was isolated from the F17 serum pool (F17 IgG) or from a pool of normal rat sera (non-immune IgG) by standard methods as previously described^{9,10}. Samples from the infected or mock infected cytoplasmic (9×10^6 c.p.m.) or nuclear (3×10^6 c.p.m.) extracts were mixed with $30 \mu\text{g}$ of F17 IgG or non-immune rat IgG in 150- μl reaction mixtures containing RIPA buffer. Reaction mixtures were incubated in 0.4-ml plastic disposable centrifuge tubes (Beckman) for 18h at 4°C . Goat serum anti-rat IgG ($28 \mu\text{l}$) was added and the incubation continued for 2h at 37°C . The contents of the tubes were layered on 180 μl sucrose (10% sucrose in RIPA buffer) and centrifuged for 1.5 min at 10,000g in a Beckman 152 microfuge. The supernatants were removed by suction and the precipitates were washed three times by vigorous mixing with 150 μl of RIPA buffer, then resuspended in 20 μl of sample buffer⁸ without 2-mercaptoethanol. Radioactivity in an aliquot of each sample was determined. An average of 0.26% of input counts was in control precipitates (infected cytoplasmic extracts against non-immune IgG, or mock infected cytoplasmic extracts against both non-immune and F17 IgG) whereas 0.69% of input counts were in precipitate from infected cytoplasmic extract against F17 IgG. The precipitates of the corresponding controls of the nuclear extracts contained an average of 0.64% of input counts, whereas the precipitate from infected nuclear extract against F17 contained 1.66% of input counts. Equal volumes (7 μl) from each precipitate suspension were boiled for 4 min and analysed by sodium lauryl sulphate polyacrylamide gel electrophoresis in 9-10-cm gradient slab gels (8-21%) as previously described⁸ except that slabs were 0.75 mm thick. Extracts of mock-infected and Ad2-infected cells were also included to serve as markers. These were obtained as described above except that cells were labelled with ³⁵S-methionine ($25 \mu\text{Ci ml}^{-1}$) for 1h only (7.5-8.5h after infection). Two other cultures, infected and mock infected, were prepared by the cycloheximide enhancement method⁸. Briefly, cycloheximide ($25 \mu\text{g ml}^{-1}$) was added 1h and ara C ($20 \mu\text{g ml}^{-1}$) at 4h after infection. At 7h after infection cells were washed twice with warm medium containing ara C ($20 \mu\text{g ml}^{-1}$), and labelled for 1h with ³⁵S-methionine as described above. The cells were collected, washed with ice-cold PBS, precipitated with 10% trichloroacetic acid, solubilised in sample buffer, and electrophoresed on polyacrylamide gels as before⁸. After electrophoresis, gels were dehydrated in a solution of dimethyl sulphoxide, soaked in a solution of 2,5-diphenyloxazole in dimethyl sulphoxide¹⁶, dried, exposed to film at -70°C , and autoradiographs were developed. a, Uninfected cells, ara C-treated; b, infected cells, ara C-treated; c, uninfected cells, CH- and ara C-treated; d, infected cells, CH- and ara C-treated; e, infected cytoplasmic extract against F17 IgG; f, infected cytoplasmic extract against non-immune rat IgG; g, uninfected cytoplasmic extract against F17 IgG; h, uninfected cytoplasmic extract against non-immune rat IgG; i, infected nuclear extract against F17 IgG; j, infected nuclear extract against non-immune rat IgG; k, uninfected nuclear extract against F17 IgG; l, uninfected nuclear extract against non-immune rat IgG.

fractionated into cytoplasm (*e-h*) and nucleoplasm (*i-l*). F17 IgG specifically precipitated 51–55k (average 53k) and 15k polypeptides from both cytoplasmic (Fig. 1*e*) and nuclear (Fig. 1*i*) extracts of infected cells. IgG from unimmunised rats (non-immune rat IgG) did not precipitate these polypeptides from infected cell cytoplasmic (Fig. 1*f*) or nuclear (Fig. 1*j*) extracts. Neither F17 nor non-immune rat IgG precipitated 53k and 15k polypeptides from uninfected cell extracts (Fig. 1*g* and *k*, and *h* and *l*, respectively). Several minor host bands were precipitated nonspecifically by all IgG samples. The swelling at the top of the lanes of Fig. 1 representing immunoprecipitated samples is caused

polypeptides⁸. We have observed, however, a 53k polypeptide in infected cells by labelling in hypertonic medium (unpublished results), which greatly reduces the synthesis of host proteins relative to viral proteins. Thus both 53k and 15k polypeptides can be detected, in special labelling conditions, that could correspond to the immunoprecipitated polypeptides. We have also observed 53k and 15k in various protein labelling and immunoprecipitation experiments: (1) with and without pretreatment of cells with cycloheximide; (2) with cells labelled between 5 and 8h, 7 and 7.5h, 8 and 11h (but not 2 and 5h), 6 and 10h followed by a 12-h chase, and both with and without 2 mM phenyl-

Fig. 2 Autoradiogram of polyacrylamide slab gel, showing electrophoretic separation of polypeptides precipitated by Ad1-SV40 IgG from cytoplasmic and nuclear extracts of Ad2 early infected KB cells. The same markers and extracts described in the legend to Fig. 1 were used, and precipitated in the same manner, except that 20 μ g of Ad1-SV40 IgG or non-immune hamster IgG was used. Goat serum anti-hamster IgG (10 μ l) was added after 18h of incubation at 4°C. Fraction of input counts recovered in precipitates: cytoplasmic controls, average 0.23%; infected cytoplasmic extract against Ad1-SV40 IgG, 1.58%; nuclear controls, average 0.61%; infected nuclear extract against Ad1-SV40 IgG, 3.99%. Placement of the lanes is identical to that described in Fig. 1 except that Ad1-SV40 IgG replaced F17 IgG and non-immune hamster IgG replaced non-immune rat IgG.

by IgG (150k). In this experiment samples were not treated with 2-mercaptoethanol to reduce disulphide bonds as this dissociates IgG into 50k and 25k subunits that distort the lower gel portions. Mercaptoethanol treatment did not affect the 53k and 15k bands, nor reveal any additional virus-specific polypeptide bands. The protein band immediately below the IgG in Fig. 1*e* and *i* was not present when mercaptoethanol was used, and therefore probably is an artefact of antigen-antibody dissociation or electrophoresis, and not a high molecular weight virus induced polypeptide.

As Fig. 2 shows, Ad1-SV40 IgG also specifically immunoprecipitated 53k and 15k polypeptides from the cytoplasm of infected cells (Fig. 2*e*), and 53k but not 15k from the nucleoplasm (Fig. 2*i*). The Ad1-SV40 titre to 15k seems to be lower than that of F17, since it precipitated less 15k from the cytoplasm, and apparently none from the nucleus. Neither 53k nor 15k were precipitated from uninfected cell extracts by Ad1-SV40 IgG (Fig. 2*g* and *k*), or from infected (Fig. 2*f* and *j*) or uninfected (Fig. 2*h* and *l*) cell extracts by non-immune hamster IgG. Ad1-SV40 IgG also precipitated large amounts of 75k, as expected from our earlier studies with Ad1- and Ad2-SV40 antisera proving that 75k is expressed in the Ad1- and Ad2-SV40-induced hamster tumours^{9,10}. Also precipitated were diffuse bands of 43k and 36k polypeptides (Fig. 2*e* and *i*), which are degradation products of 75k (ref. 11 and unpublished data). Ad2-SV40 IgG gave identical results (data not shown). Saborio and Öberg¹² reported that Ad2-SV40 IgG precipitated 72k, 67k, 60k, and 45k polypeptides from extracts of labelled Ad2-infected HeLa cells. How these correspond to the polypeptides we have observed is not known. It is possible that they did not detect our 15k polypeptide because of the low titre of Ad2-SV40 IgG against this polypeptide.

Unequivocal identification of the 53k and 15k polypeptides as virus-specific is difficult by radioimmune precipitation and gel electrophoresis, because of possible cross-reacting antibodies, nonspecific precipitation and proteolytic breakdown of immunologically reactive viral proteins. At 15k polypeptide is visible in extracts without immunoprecipitation, especially after cycloheximide pretreatment, but a 53k polypeptide usually cannot be resolved from the large background of host

methylsulphonylfluoride (protease inhibitor); (3) with two independent pools of F17 antisera; (4) with and without absorption of F17 antiserum with extracts of uninfected KB cells. In these various experiments 53k was observed as a fairly diffuse band as in Figs 1 and 2. Some variability was observed in the polypeptides in the 15k region of gels. Occasionally a polypeptide of about 17k was observed in cytoplasmic extracts (Fig. 1*e*), and one of 11k in nuclear extracts. The 11k polypeptide apparently induced by Ad2 and localised in the cell nucleus (unpublished), was also precipitated by non-immune IgG, probably nonspecifically. Also the 15k polypeptide band sometimes appeared as a doublet and even as a triplet. The significance of this variability is unclear: the 'extra' bands may represent some type of modification of 15k. It is also possible that F17 and the Ad-SV40 antisera contain low titres of antibodies against viral polypeptides of 15–17k in addition to 15k.

Our major finding is that three antisera (F17, Ad1-SV40 and Ad2-SV40) expected to contain antibodies against Ad2 transforming protein(s) specifically precipitate 53k and 15k polypeptides. The synthesis of both polypeptides in Ad2-transformed rat cells, Ad-SV40 hamster tumour cells, and Ad2-infected human cells, suggests (but does not prove) that they are virus coded. Since F17 contains only the left 14% of the Ad2 genome⁴, which includes transforming genes, these polypeptides are strong candidates for transforming proteins. It is important to note that F17 cells apparently express Ad2 mRNA sequences in addition to those of presumptive transforming genes; that is Ad2 transforming genes map somewhere within MP 0.01 and 0.075 (ref. 6), whereas F17 may express roughly MP 0.03–0.10 as mRNA⁵. It is therefore possible that either 53k or 15k (or both) is not a transforming protein. The only evidence available on this point is from Lewis *et al.*¹³, who have translated *in vitro* Ad2 mRNA, hybridisation-purified from F17 cells, into a diffuse 44–50k and a prominent 15k polypeptide. The 15k polypeptide was produced by translation of mRNA selected by hybridisation to either *HindIII*-G (MP 0–0.075) or *HindIII*-C (MP 0.075–0.17), but not *HpaI*-E (MP 0–0.041). As *HindIII*-G can transform cells this argues that the 15k polypeptide may not be a transforming protein, unless there is more than one 15k, or unless the 3'-

terminal sequences (complementary to *HindIII*-C) in the mRNA for the 15k polypeptide are superfluous. The 44–50k polypeptide mapped to the left of 15k and thus its gene is closer to the transforming region. Of course it is not known whether our 53k and 15k correspond to the 44–50k and 15k polypeptides of Lewis *et al.*, but if so, then 53k may be a better candidate than 15k as a transforming protein. Positive identification of Ad2-transforming protein(s) will require transformation-defective mutants, as well as antisera against transformed cells that express only transforming gene(s).

We thank Drs S. J. Flint, P. A. Sharp and P. H. Gallimore for the F17 cell line, Dr R. V. Gilden for Ad1- and Ad2-SV40 antisera, Dr H. T. Thornton for assistance with cell culture, and Barbara Smith for technical assistance. This work was supported by funds from the NIAID and by a contract with the Virus Cancer Program of the NCI. W.S.M.W. is a recipient of a research fellowship from the MRC of Canada. M.G. is a recipient of a research career award from the NIH.

Growth regulation of cells grown in suspension culture

VARIOUS aspects of a cell's growth cycle can be manipulated in tissue culture. For example, the initiation of DNA synthesis and, in some cases, culture growth, can be enhanced by serum¹ and platelet² components, polypeptides purified from growth-conditioned medium³ and urine⁴, insulin⁵, corticosteroids⁶, prostaglandins⁷, cyclic nucleotides (see, for example, ref. 8) and proteolytic enzymes⁹. In addition, at least three purified proteins can initiate DNA synthesis in fibroblast-like cells—nerve growth factor¹⁰, epidermal growth factor¹¹ and fibroblast growth factor^{12,13}. Disturbance of the culture medium directly over the cultured cells also induces DNA synthesis¹⁴. Fibroblast-like cells have been used in most of these studies, and they grow tightly associated with the culture dish and are strongly anchorage dependent for division^{15,16}. Given the strong anchorage dependence of the test cells, two alternatives could account for the induction of DNA synthesis and growth by the diversity of conditions and "factors" outlined above. The first would ascribe the effects of these compounds to interactions on the cell surface with a suitable receptor. These are hormone-like interactions, thought to be exemplified by compounds such as insulin and purified

growth factors¹. The second alternative represents interactions which function directly through alterations of cell anchorage. For example, the growth stimulating effects of the proteases are presumably affected by modification of the cell-substratum (anchorage) interaction¹⁷. To distinguish between these two alternatives, it should be sufficient to assay the effects of serum and a purified growth factor on the initiation of DNA synthesis in an anchorage-dependent cell line, and on a variant which grows in suspension culture. If serum and the growth factor were equally effective in both cell lines, then a disturbance in anchorage could not account for the mitogenic activity, ruling out the second alternative. The first, hormone-like, mechanism, however, would be excluded if the growth factor was unable to induce DNA synthesis in the cells grown in suspension. The following experiments support this latter possibility by showing that fibroblast growth factor^{12,13} does not affect the growth of myoblast cells grown in suspension culture.

The cells examined were a rat myoblast line (L6) derived from embryonic skeletal muscle¹⁸ and a subline (M3A) derived from it which grows in suspension culture¹⁹. Although M3A does not fuse to form myotubes, its growth characteristics and regulation of some muscle enzymes are the same as the attached parent cell line¹⁹. When tested in several concentrations of serum, the serum dependence for growth of M3A and L6 cultures is similar, with the M3A cells responding slightly less well to low serum concentrations (Fig. 1). Finally, 3T3A, an anchorage-dependent line whose response to various growth factors has been well defined²⁰, was used as a control to test the efficiency of the purified growth factor.

A growth promoting factor for fibroblast cells, initially found in pituitary extracts¹² and subsequently purified¹³, was used because it seems to initiate DNA synthesis in a wide variety of cell types¹³. This factor, termed fibroblast growth factor (FGF), was purified²¹ and used in the following studies. The assay for the initiation of DNA synthesis was done on sparse quiescent cells²⁰. Table 1 shows that purified FGF stimulated the incorporation of ³H-thymidine by resting 3T3 cells as described before²⁰, demonstrating that the FGF preparation was functional on the fibroblasts.

When attached L6 myoblasts were tested for stimulation of DNA synthesis by FGF in conditions identical to those described for 3T3, there was an increased incorporation of ³H-thymidine into trichloroacetic acid (TCA)-precipitable material (Table 1). The greatest stimulation was with FGF

Table 1 Effect of FGF on fibroblasts, anchorage-dependent myoblasts and suspension grown myoblasts

Additions	Cell lines and relative increase in thymidine incorporation		
	3T3A	L6	M3A
None	1	1	1
10% Serum	17.1	7.1	5.8
FGF	4.5	1.4	1.1
Insulin	—	2.0	1.0
Hydrocortisone	1.0	1.1	0.9
Hydrocortisone + insulin	3.3	2.1	1.1
FGF + insulin + hydrocortisone	6.6	7.0	1.2

Cells were plated in 10% foetal calf serum, and after 2 d the serum concentration was reduced to 0.5%. 48 h later the indicated reagents were added to the growth-inhibited cells (density between 5×10^4 and 2×10^5 cells per 60-mm dish). 18 h later the incorporation of ³H-thymidine into TCA-precipitable material was assayed as described²⁰. The concentrations of the reagents (ng l⁻¹) were: FGF, 100; insulin, 1,000; hydrocortisone, 1,000. Data are presented as the increase, relative to control cultures in 0.5% serum, of the ³H-thymidine incorporation. Background incorporation in control cultures was 5,100 c.p.m. for 3T3A, 6,800 c.p.m. for L6 and 7,900 c.p.m. for M3A. The data are the means of triplicate determinations, with an average error between samples of less than 10%. The experiment was repeated three times with similar results.

in combination with insulin and hydrocortisone. But when the suspension-grown cell line, M3A, was assayed in the same conditions there was little or no stimulation of ^3H -thymidine incorporation with the defined reagents (Table 1), although the stimulation achieved by the addition of whole serum was similar to that found with L6. Thus the combination of FGF, insulin and hydrocortisone, compounds which act synergistically with FGF to stimulate DNA synthesis 3T3 cells²⁰, stimulate anchorage-dependent L6 cells but not their suspension-grown variant. Since both L6 and its anchorage-independent derivative M3A are responsive to serum stimulation to approximately the same extent (Fig. 1 and Table 1), the possibility that FGF and its synergists can replace the serum requirement of these cells is ruled out. In addition, if M3A had lost its hypothetical surface receptors for FGF, then FGF has no rate limiting physiological role in the growth regulation of these cells by serum.

Fig. 1 Serum dependence for culture growth of L6 and M3A cells. Cells were plated on day 0 in 60-mm tissue culture (L6) or Petri dishes (M3A) in 5 ml of medium containing the indicated concentration of foetal calf serum. The cell number was then followed as a function of time. *a*, L6; *b*, M3A; Δ , 0.2% serum; \square , 0.5% serum; ∇ , 1% serum; \star , 2% serum; \times , 10% serum.

If it is generally true that cells grown in suspension culture are not sensitive to the defined "factors" which stimulate the growth of attached, anchorage-dependent cells, then some caution should be exercised in interpreting results based exclusively on attached cells. Of the conditions that tend to stimulate growth of attached fibroblast-like cells, there seems to be one underlying factor—the disturbance of the limiting cell membrane. For example, insulin stimulates growth^{5,20} and is weakly proteolytic²²; the corticosteroids are lipophilic and interact nonspecifically with membranes. Nerve growth factor stimulates the growth of fibroblast-like cells, presumably through its proteolytic subunit¹⁰, as do

various proteolytic enzymes^{9,17,23}. Since overt proteolytic treatment of anchorage-dependent cells inhibits division by rendering the cells into suspension, it follows that the extent of proteolysis that initiates cell division is quantitatively less. In addition, disturbance of the medium above cells triggers DNA synthesis¹⁴, perhaps perturbing the cell-substratum interactions by exerting a weak shear force on the cells. Various inorganic ions are nonspecifically mitogenic²⁴, perhaps for the same reason. As the degree of cell anchorage is critical in the initiation of cell division (see, for example ref. 17), it is possible that any reagent which disturbs this cell surface interaction in attached cells may trigger one or more rounds of DNA synthesis and cell division. Such a reagent need not be proteolytic. For example, several purified proteins lacking proteolytic activity induce neurite retraction in C1300 neuroblastoma cells, presumably by weakening the cell-substratum interaction required for neurite extension²⁵.

In summary, if purified (serum) growth factors are functioning in a hormone-like manner by interacting with specific cell surface receptors, then one would predict that anchorage-dependent and independent lines should respond similarly if their serum response is the same. As this hypothesis is contradicted by the data reported here, it is possible that "growth factor" responses of attached cells are not mediated through specific surface receptors, but through less specific perturbations of the cell-substratum interaction. For anchorage-dependent cell lines, anchorage is necessary but not sufficient to regulate cell division. By using anchorage-independent cells for the characterisation of growth promoting activities, it is possible to eliminate one experimental variable.

Effect of 3-acetylpyridine on tissue differentiation of the embryonic chick limb

3-ACETILPYRIDINE (3-AP) and 6-aminonicotinamide have a teratogenic effect on the development of the chick limb but have no effect of coadministered with nicotinamide¹. This

has led Caplan to the hypothesis that nicotinamide has a crucial role in the spatial organisation of muscle and cartilage in the developing limb, high levels of nicotinamide specifying muscle, and low levels cartilage; with even the possibility that a metabolic gradient related to the blood supply could provide the positional information specifying the pattern of muscle and cartilage²⁻⁵. The evidence for this hypothesis is based both on *in vivo* and *in vitro* studies, the latter claiming to show that 3-AP enhances chondrogenesis and inhibits myogenesis in cultured limb mesenchyme cells. As regards the *in vivo* effects, it is suggested that the gross muscle hypoplasia observed might be accounted for in terms of 3-AP switching the differentiation of mesenchyme cells from a myogenic fate to a chondrogenic one. This seemed to us to be an unlikely explanation, since the chondrogenic and myogenic tissues are already physically separated at stages when 3-AP is still known to have an effect (as late as 13 d of incubation). It seemed much more likely that 3-AP was affecting muscle growth rather than its differentiation. We therefore made a histological study of the effect of 3-AP, and found that it was a potent destroyer of the peripheral nerves, and that there is no evidence to support the view that it affects mesenchyme differentiation.

Eighty-four White Leghorn embryos at 3 d of incubation were windowed and sealed with Sellotape. At 6 d of incubation, 2 mg of 3-AP (Sigma) in 100 μ l of distilled water were dropped on to the embryo membranes of 56 of these, the remainder serving as controls. The eggs were resealed and incubated for periods from 6 h to 5 d when the embryos were removed and the right wings and legs fixed in Karnovsky's solution and embedded in Araldite. Transverse sections (1 μ m) were taken from a region of the leg 1.5 mm proximally from the distal end of the tibia, where the thin appearance of treated limbs is most marked, and from the wing mid-way along the radius and ulna, limbs being measured and marked in Araldite before cutting. The sections were stained with Toluidine blue, and areas measured from camera lucida drawings with a Stanley Planimeter. By 3 d after treatment, the usual gross morphological appearance of 3-AP treatment (described as 'muscle hypoplasia' and evident particularly as thinness of the legs) was discernible, and by 5 d it was marked, with embryos being

reduced in wet weight by up to 30% and their legs, although of approximately normal length, reduced by up to 50% in thickness. As is usual in both teratogenic and genetic defects, the legs were affected much more markedly than the wings, and there was considerable variation in expression of the defects, ranging from almost normal appearance to death.

At 6 d of incubation, when treatment began, the cartilage of both wing and leg is well differentiated but ossification has not yet begun. The dorsal and ventral muscle masses are clearly visible, and the splitting division into individual muscles is just beginning to be evident, but the tendons have not yet begun to develop. The physical separation of chondrogenic from myogenic tissues should be stressed, the cartilage being surrounded by a well defined perichondrium. The nerves at this stage extend as far as the wrist and ankle. Sections were taken from five legs which had been left 5 d after treatment, together with five equivalent controls (Fig. 1). Notable is the absence of tendons, and the reduction in the area of the cartilage of the treated animal (49% reduction in the average area of the tibia). It is these factors, together with the reduction in the loose mesenchyme which give the limb its characteristic thin appearance at this stage; there is in fact virtually no muscle normally present in this region so the usual description of 'muscle hypoplasia' is inappropriate. Further, nerves could not be found in the treated legs, although they were well developed in the controls.

This last result has been noted previously by Tanaka *et al.*⁶, although they remained uncertain as to its exact importance. The effect is apparent on peripheral rather than on spinal nerves, although the neurotoxic effect of 3-AP on adult brains has been noted by several authors⁷.

Since 3-AP is described as specifically affecting differentiation of the muscles, sections were taken from the muscle-rich region of the wing described above. Sixteen treated wings at various stages were examined, together with 12 controls. The muscle up to 2-3 d after treatment was substantially normal, though somewhat smaller than the controls; and the muscle blocks began to split up, again as normal, giving rise to individual muscles. After 3 d the muscles began to degenerate. There was no significant

Fig. 1 C, Cartilage; M, muscle; T, tendon; N, nerve; BV, blood vessel. *a*, Transverse section of leg of 11-d-old control animal. The cartilage element is the tibia. *b*, Transverse section of leg of animal treated with 3-AP at 6 d, 5 d after treatment. Tendons and nerves are absent and the cartilage is smaller in area.

Fig. 2 R, Radius; U, ulna; N, nerve; M, muscle; BV, blood vessel. *a*, Enlargement of central region of transverse section of normal 6-d-old chick wing (that is, at time of treatment). Nerves are clearly present. *b*, Same region of limb treated with 3-AP, 24 h after treatment (that is, at 7 d of incubation). The nerves present at 6 d have now been destroyed, but the muscle blocks are not obviously affected.

reduction in the area of the cartilage; the most striking effect was on the nerves. In embryos examined 6–12 h after treatment, some nerves were already absent. Examination at 24 h or later showed all limbs except one to be completely devoid of nerves (Fig. 2).

These results show that 3-AP has a deleterious effect on the growth of all the tissues in the developing limb, that on nerves being the most marked. Since it is well known that denervation results in muscle degeneration^{8,9}, the long term effect of 3-AP on muscles is most probably mediated by its effect of destroying peripheral nerves within about 24 h of treatment. The absence of tendons may also have an adverse effect on muscle development. 3-AP can also reduce the radial growth of cartilage viewed in cross section, although the length of the cartilaginous elements is not affected, perhaps because of interference with cell division, leaving matrix secretion unaffected. Conversely, our preliminary results suggest that 6-AN does affect matrix secretion. The greater effect on the leg when compared with the wing, can be related to the comparatively small amount of radial growth in the radius and ulna during the experimental period compared with the tibia (twofold as opposed to ninefold for the latter).

The effect of 3-AP on the tissues of the limb bud as revealed by histology shows clearly that it does not act specifically by repressing myogenesis and enhancing chondrogenesis in the manner proposed by Caplan, but rather indicates a deleterious effect on various cell types including cartilage, mesenchyme, muscle and tendon, but which is particularly marked in the case of peripheral nerves, these being almost totally destroyed after only 24 h treatment, and whose absence must lead to serious defects in the later development of the muscles. The biochemical mechanisms involved in the specification of muscle and cartilage remain quite unknown.

Development of the locust ocellus

WORKERS interested in retinal development have been attracted by the iterative unit structure and prolonged development time of the compound eye of hemimetabolic insects^{1–4}. By comparison, the ocellus of the adult locust (*Schistocerca gregaria*) is a simple retina composed of only 1,000 receptive elements with a very loose cartridge-like division of receptors and underlying synaptic plexus. The plexus is composed of receptor terminals, the arborisations of second-order cells and glial elements. Most of the second-order contributions to this structure are composed of the repeatedly branched endings of the so-called giant cells, on to which the retina is highly convergent. The structure is so simple that here I report the possibility of examining developmental mechanisms at the single-cell level.

In eggs maintained at $28^{\circ}\text{C} \pm 0.5^{\circ}\text{C}$ the ocelli first become visible through the embryonic cuticle as small white patches about 178 h before emergence (mean total development time 380 h). Sections cut at this stage show the ocelli as cone-shaped aggregations of 'tailed' epidermal cells. No distinct growth cones are present and few neurotubules are found in the cytoplasm. By 165 h before emergence the epidermal cells have extended 60–70 axonal processes $225\text{ }\mu\text{m}$ long, deep into the brain. This gives the embryonic retinula axons a growth rate of about $17\text{ }\mu\text{m h}^{-1}$, somewhat slower than the $25\text{ }\mu\text{m h}^{-1}$ recorded for *Lucilia* compound eye retinula cells⁵. The axons are rich in neurotubules and the cytoplasm contains an abundance of ribosomes and granules.

On entering the embryonic neuropile the axons establish conical growth cones rich in filopods. During growth to this point growth cones are typically spear shaped. Within the brain the filopods of the retinula cells make electron dense contact with certain neuropilar processes. At this

Fig. 1 *a*, A 10- μ m wax section, stained by the Power-Bodian technique⁷, of the lateral ocellus of a newly emerged hopper. The ocellar nerve containing about 70 retinula cell axons skirts the protocerebral lobe and enters the protocerebrum near the midline. Most such axons terminate in the dorsal pars intermedia. Many of these axons are derived from rhabdomeless cells and thus cannot be functional at this stage. The bar represents 50 μ m. *b*, The retinal axons of the newly emerged hopper appear tightly grouped around the second-order axons, only three of which lie within this section. The bar represents 25 μ m. *c*, The lateral ocellus of a second instar locust during the intermolt period. Note the vast expansion in the number of cells in the retina; retinula cell axons are absent from the length of the ocellar nerve. Branches pass from the second-order cells into the descending retinal bundles. The darkly stained group of cells (top left) are thought to represent the next group of retinula cells to be recruited from the surrounding epiderm. The bar represents 100 μ m.

stage no second-order processes can be detected in the descending bundle of retinula cell axons.

Sections taken shortly before emergence (380 h) show the presence of five large second-order cell profiles in the

ocellar end of the lateral ocellar nerve. The second-order profiles are readily distinguished from the receptor terminals because of their white cytoplasm. Two hours after emergence the retina cell axons still extend within the brain but only to the top of the protocerebral lobe (Fig. 1*a, b*). This positional change is not due to any change in length of the retinula cells but rather to a sustained growth of the second-order axons and an associated increase in the length of the ocellar nerve. Synapse-like structures are present in the ocellar nerve 6 h before emergence but usually in association with dense-cored vesicles.

After emergence into the light, synaptic structures proliferate rapidly. The lateral ocellar second-order axons extend in the course of the first two instars until all the retinula cell axons lie within the proximal half of the ocellar nerve (Fig. 1*c*). New retinula cells are recruited from the surrounding epiderm at each moult, and their axons are incorporated into the synaptic plexus.

Examination of silver-stained, semi-thin and thin sections shows increase in the complexity of the second-order giant cell arborisations with each moult, retinula cell ingrowth apparently preceding the addition of branches to the giant cells. The presence of two axons connecting the median ocellus with the lateral ocellus^{5,6} makes possible the staining of these two cells' arborisations by the diffusion of cobalt chloride into the median nerve (Fig. 2*a*). In the adult these two arborisations consist of repeated branching into the paths of the descending retinula cells. Stains of earlier instars reveal a much reduced branching structure. It is interesting to speculate that the apparent contact guidance of second-order cells from the brain into the ocellus may be followed by the advance of long collaterals from the second-order cells into retinula cell bundles through a similar mechanism in which the newly developed retinula axons compete for collaterals. Support for this theory comes from adult brains that occasionally contain a third supernumerary median to lateral cell^{5,6}. In this circumstance the arborisations of each individual cell are simpler than in the normally innervated retina (Fig. 2*a* and *b*). Manipulative experiments are in progress to confirm these observations and to determine what other parameters may affect the form of the second-order cell

Fig. 2 *a*, Cobalt stain of the two latero-median axons viewed as a whole mount of the adult lateral ocellus. *b*, Whole mount of an adult lateral ocellus which contains a third latero-median axon. In spite of the presence of an extra nerve there is no commensurate increase in the total number of collaterals generated. The bars represent 100 μ m.

patterns. Further structural details of ocellar development are to be discussed elsewhere.

I thank Dr L. J. Goodman for helpful discussions. This work was funded by a grant from the SRC.

Plasmodium falciparum gametocytogenesis *in vitro*

THE mechanism of sexual reproduction among malaria parasites is coming under increasing scrutiny. Gametogenesis is being unravelled by electron microscopy¹ and by kinetic studies². Gametocytogenesis on the other hand remains poorly understood in spite of earlier work^{3–5}. The development of *Plasmodium falciparum* gametocytes is particularly intriguing because in man they develop in the deep tissue spaces, especially the spleen and bone marrow. The immature stages only rarely appear in the peripheral blood and as a result have escaped detailed experimental investigation until now. Furthermore, it has long been suspected that their development is prolonged³, taking 8–12 d, although there are suggestions to the contrary^{6,7}. Immature gametocytes of *P. falciparum* have recently been reported in cultures thought to be composed only of asexual parasites⁸. I have used a similar microculture technique which has permitted the development *in vitro* of morphologically mature *P. falciparum* gametocytes and present here some preliminary observations on the process of gametocytogenesis in *P. falciparum* infections.

Parasites were obtained from 27 unselected patients aged 6 months–6 yr. Parasitaemias were measured by standard techniques. Heparinised venous blood was washed once with

medium 199. From each patient cultures were set up composed of medium 199 supplemented with 200 mg% glucose, 30 mg% glutamine, 25% (v/v) foetal calf serum and 2.5% (v/v) of washed packed blood cells. Aliquots (200 μ l) of the culture were dispensed into flat-bottomed 6-mm tissue culture microplates (Linbro) and maintained in a CO₂ incubator (5% CO₂ in air) at 37 °C. The medium was replaced every 2 d. The culture was sampled each day by taking one 200- μ l aliquot for the preparation of blood smears.

Gametocytes developed in 80% of cultures; that is in 22 taken from 27 different subjects. The cultured gametocytes were classified into stages of development⁹ based on the detailed morphological descriptions made by earlier workers from post-mortem specimens and tissue biopsies^{4,10}. As a result a sequential pattern of development for the growing gametocytes was demonstrated (Fig. 1). The significance and relevance of this morphological pattern to the developmental biology of *P. falciparum* gametocytes is under study. In man the gametocytes of *P. falciparum* first appear in the peripheral blood about 10 d after the asexual parasites^{3–5}. The cultures *in vitro* give direct confirmation that the 10 d are occupied by the progressive development of the gametocytes rather than by an inductive process and a shorter period of development⁷. The mean culture life was 8.8 d during which all the immature gametocytes grew to at

*Gametocytes classified according to Hawking *et al.*⁹ (see Fig. 1).

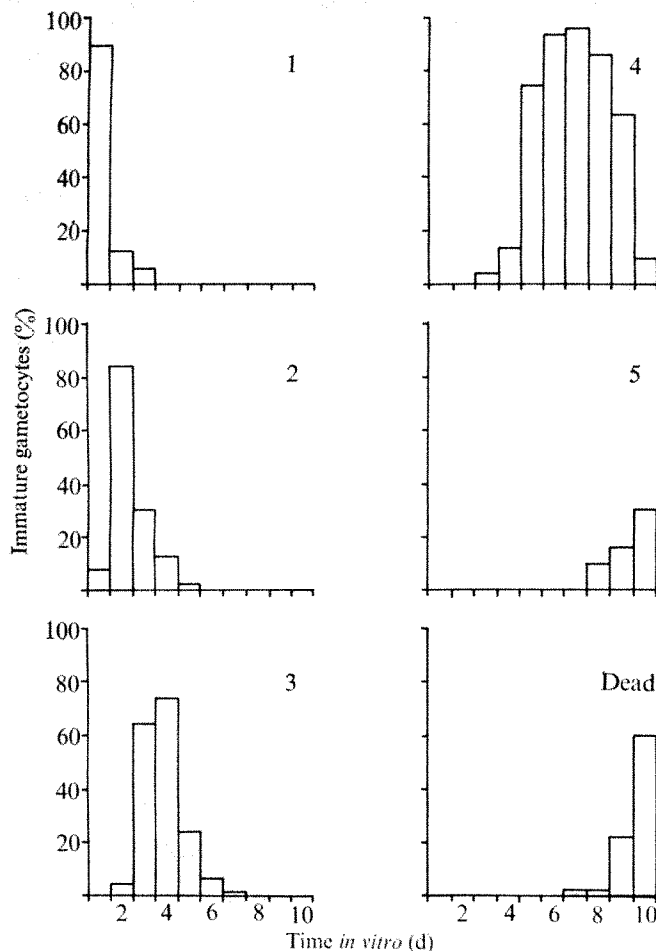

Fig. 1 Sequential development of immature gametocytes of *Plasmodium falciparum* grown *in vitro*. The gametocytes were classified into stages of development according to the outline of Field and Shute⁴ and modified by Hawking *et al.*⁹; 5 developmental stages were recognised. (1) Rounded parasite, not filling the red cell; (2) parasite irregular shape, slightly elongated, not filling the red cell; (3) parasite elongated, red cell slightly distorted; (4) parasite elongated, red cell very distorted; (5) mature crescentic gametocyte. Dead gametocytes were identified as parasites within red cells that were either elongate and very densely stained or were rounded up and lightly stained. These probably represent gametocytes that died at different stages of their development.

least the 4th stage of development and some cultures produced up to 32% of morphologically mature gametocytes. There is known to be an interval of 1–2 d between the development of morphological maturity and the attainment of functional maturity¹¹. It seems that the longevity of the cultures, limited so far by the ability of red cells to survive prolonged periods *in vitro* at 37 °C has prohibited the development *in vitro* of functionally mature gametocytes.

The asexual parasites in the original sample of blood grew *in vitro* and after 36–48 h significant reinvasion of erythrocytes by the liberated merozoites was obtained (mean multiplication rate of 4.8 times). During the first 24 h *in vitro* no increase in parasite numbers was recorded and yet immature gametocytes were detected (Table 1). It is clear therefore that very young gametocytes, as newly formed rings, invade the peripheral blood along with the young asexual rings that come from the same population of schizonts. Both populations then withdraw to the deep tissues to complete their development, the asexual parasites taking a further 18–24 h and the gametocytes 8–9 d. Phillips *et al.*⁸ have further reported that ring-stage parasites derived from the peripheral blood and cultured *in vitro* to the schizont stage can subsequently give rise to both sexual and asexual lines of *P. falciparum* parasites *in vitro*.

Gametocytogenesis in *P. falciparum* infections within

adult humans has been positively correlated with the onset of clinical malaria rather than simply with increasing asexual infection⁷. The event is probably not therefore the consequence of an intrinsic process that gives an increasing probability of detecting gametocytes from a higher compared to a lower asexual infection. Only 59% of my cultures started from patients with asexual parasites alone in their peripheral blood produced developing gametocytes *in vitro*, compared with 100% of the cultures taken from patients with an infection that had already started to produce mature gametocytes *in vivo*. These results confirm that gametocytes are not produced immediately the blood infection begins, rather there is a definite point in the infection when gametocytogenesis starts for the first time. Once gametocyte production has begun from the persisting asexual infection, however, then each successive schizogony produces further gametocytes. Four patients studied on more than one occasion supported this view (Table 2). It is suggested that there is a trigger for the start of gametocytogenesis but once the process is established within an infection then gametocyte production becomes an intrinsic part of the life cycle.

The culture technique described has opened a new area of the life cycle of *P. falciparum* to detailed investigation. The preliminary observations confirm the prolonged development of *P. falciparum* gametocytes. They also show that once gametocyte production has begun each schizogony is responsible for fostering sexual reproduction the elements of which make a temporary appearance in the peripheral blood before withdrawing to the deep tissues.

Cell surface design

CONSIDERATIONS of membrane fluidity (see refs 1–5) have often involved schematic representations of the cell plasma membrane and underlying cytoskeletal structures^{3–5}. But, although intended to show how microtubules, microfilaments and so on might interfere with the mobility of membrane components, such models have not been drawn to scale. Usually microtubules and microfilaments seem much smaller than the plasma membrane, whereas the reverse is true. Thus, it has not been possible to evaluate fully the relative importance of plasma membrane and cytoskeleton in influencing cell surface dynamics. I have therefore tried to draw these various elements to scale. Since the data come from heterogeneous sources (fibroblasts, muscle cells, amoeba, plant cells, epithelial cells and lymphocytes) it is clear that the organisation of the various structures represented here can only be hypothetical and does not correspond to a known structure in a given cell type.

Figure 1 is a representation of such a structure; it shows a section of microvillus (MV), with actin microfilaments (MF), α -actinin molecules (α -A), myosin molecules arranged as a filament (MM); the cortical cytoplasm with microtubules (MT) and their cross bridges (c-b), the plasma-membrane (PM) with extrinsic and intrinsic proteins (drawn

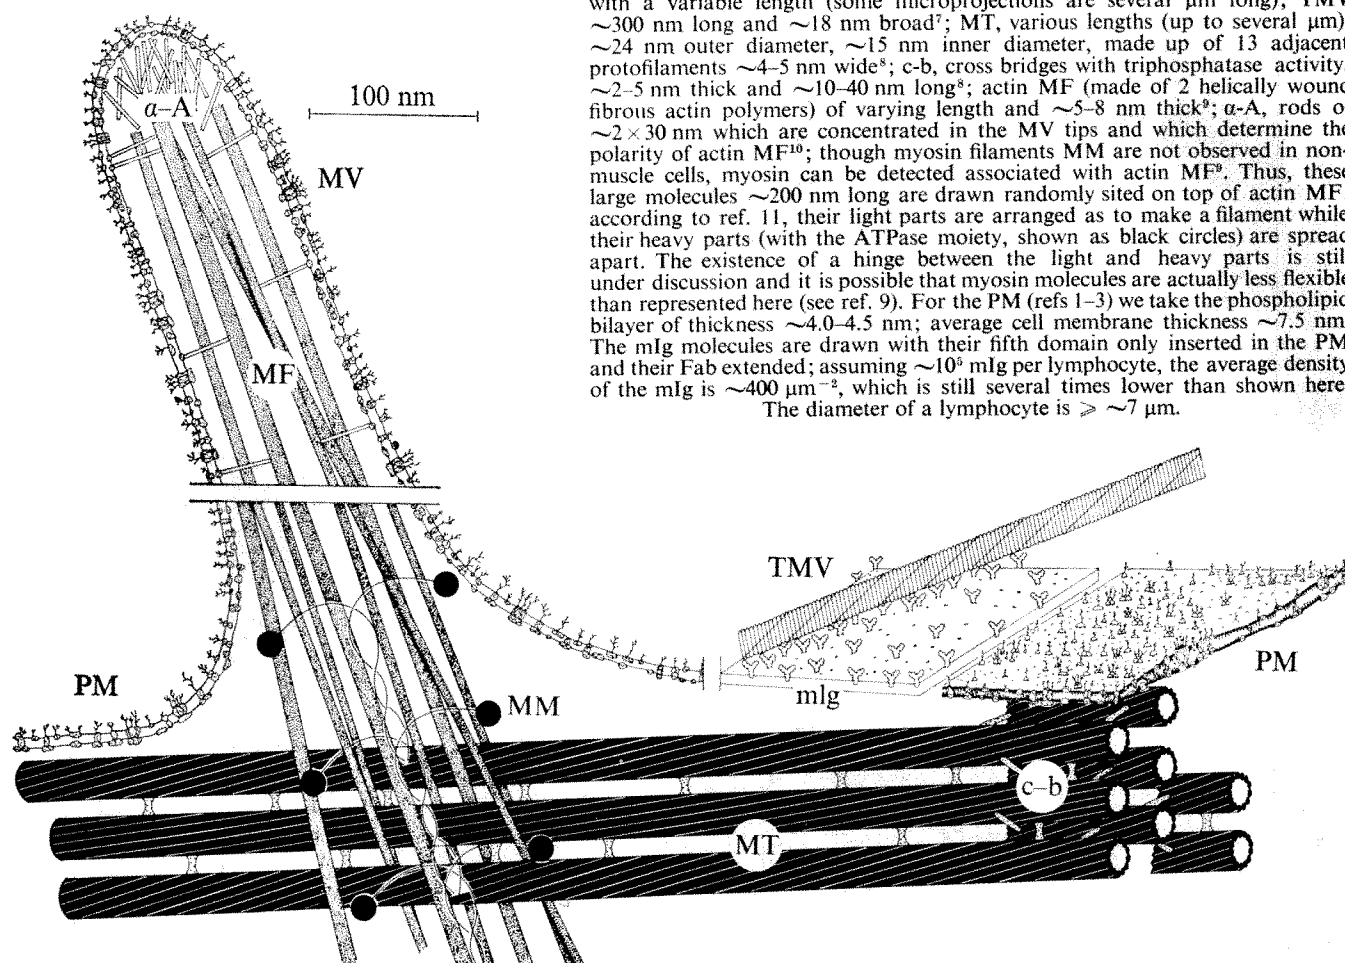

Fig. 1 Schematic representation of the cell surface; the enlargement can be estimated from the size of the tobacco mosaic virus particle (TMV) adsorbed on some mlg molecules. Actual sizes are as follows: MV diameter ~ 100 – 200 nm with a variable length (some microprojections are several μ m long); TMV ~ 300 nm long and ~ 18 nm broad⁷; MT, various lengths (up to several μ m), ~ 24 nm outer diameter, ~ 15 nm inner diameter, made up of 13 adjacent protofilaments ~ 4 – 5 nm wide⁸; c-b, cross bridges with triphosphatase activity, ~ 2 – 5 nm thick and ~ 10 – 40 nm long⁹; actin MF (made of 2 helically wound fibrous actin polymers) of varying length and ~ 5 – 8 nm thick⁹; α -A, rods of $\sim 2 \times 30$ nm which are concentrated in the MV tips and which determine the polarity of actin MF¹⁰; though myosin filaments MM are not observed in non-muscle cells, myosin can be detected associated with actin MF⁹. Thus, these large molecules ~ 200 nm long are drawn randomly sited on top of actin MF; according to ref. 11, their light parts are arranged as to make a filament while their heavy parts (with the ATPase moiety, shown as black circles) are spread apart. The existence of a hinge between the light and heavy parts is still under discussion and it is possible that myosin molecules are actually less flexible than represented here (see ref. 9). For the PM (refs 1–3) we take the phospholipid bilayer of thickness ~ 4.0 – 4.5 nm; average cell membrane thickness ~ 7.5 nm. The mlg molecules are drawn with their fifth domain only inserted in the PM and their Fab extended; assuming $\sim 10^6$ mlg per lymphocyte, the average density of the mlg is $\sim 400 \mu\text{m}^{-2}$, which is still several times lower than shown here. The diameter of a lymphocyte is $\geq \sim 7 \mu\text{m}$.

to the typical Singer–Nicolson pattern) and with an area which shows some receptor immunoglobulins (mlg) and belongs to a lymphocyte surface (for a complete analysis, see ref. 6).

This model is very different from all those so far published. For instance, it now seems impossible that several microfilaments or microtubules could be linked to single plasma-membrane proteins, as has usually been postulated. On the contrary, several membrane proteins might be linked to single microfilaments or microtubules, by means of elements such as α -actinin molecules or microtubule cross bridges. Furthermore, it seems unlikely that phospholipid flow is the major force driving the redistribution of membrane components in processes such as 'capping', on lymphocytes as well as on other cells. More likely, contractile microfilaments are involved in such gross cell surface rearrangements, the principal role of microtubules being more static. I have suggested elsewhere⁶ an hypothesis of how the antagonistic functions of microfilaments and microtubules might be co-ordinated. My idea is that they would confer to the cortical cytoplasm of the cell properties like those of a thixotropic gel.

Immunoperoxidase visualisation of microtubules and microtubular proteins

MICROTUBULES are ubiquitous eukaryotic organelles, formed by polymerised tubulin and presumably some additional proteins, which are involved in a wide variety of cell functions (for review see refs 1 and 2). Evidence has been presented for the existence of a dynamic equilibrium between polymerised and non-polymerised microtubular proteins³. Recently immunofluorescence of cultured cells demonstrated a fine cytoplasmic network that was believed to correspond to cytoplasmic microtubules. However, no direct evidence was presented that the antibodies stain individual microtubules, the formaldehyde fixation that was used is not known to preserve microtubules intact and immunofluorescence does facilitate comparison of the total picture of the microtubular apparatus with its appearance in histological and ultrastructural sections (horizontally or vertically) through the same cell. Moreover, the inadequate resolution of the light microscope does not allow an accurate localisation of the

non-polymerised tubulin and the study of its interaction with various cellular organelles. We have therefore developed an immunochemical technique described here that could simultaneously be used for the localisation of microtubules and tubulin in whole cells and in histological and ultrastructural sections, after adequate fixation with glutaraldehyde.

The unlabelled peroxidase-anti-peroxidase (PAP) method of Sternberger⁶ which had previously been adapted for the localisation of neurophysins⁷ seemed to fulfil the necessary criteria. In this method, the antibody associated with tubulin is allowed to react with an excess of an anti-immunoglobulin (as in the fluorescent "sandwich" method), and then, in turn, with a soluble complex of peroxidase and its antibody. The latter complex acts as an antigen and combines with the free antibody sites and may then be revealed by chemical reactions that lead to the deposition of osmium.

Before attempting to use whole cells, we have assessed whether microtubules polymerised in a cell-free system can be stained specifically with this method.

Figure 1b shows that individual microtubules polymerised *in vitro* and fixed with glutaraldehyde can, indeed, be stained by the PAP method. In the electron microscope

Fig. 1 *a*, Microtubules polymerised *in vitro* and negatively stained with uranyl acetate. Tubulin was prepared from rat brain homogenate and polymerised as described previously⁸. One drop of the solution was placed on a nickel grid coated with Formvar. After 1 min the grid was rinsed with a few drops of hexylene glycol 1 M and fixed for 1 min in 2.5% glutaraldehyde at room temperature. After rinsing with sodium cacodylate 0.1 M the grids were placed for 30 s on a drop of 0.5% uranyl acetate, then drained and dried. *b*, Microtubules polymerised *in vitro* and stained with the PAP-technique. Nickel grids with microtubules obtained and fixed as described above were placed on a drop of normal goat serum diluted 1/30 in Tris-buffered saline (TBS), pH 7.4 for 10 min. Then the grids were washed for 10 min by flotation on TBS on a rocking table. Hereafter the grids were placed for 30 min on a drop of TBS containing a 1/3,200 dilution of antibody solution II (see Table 1) and 1% goat serum. After washing in TBS for 20 min the grids were placed for 30 min on a drop of goat antiserum to rabbit immunoglobulins (1/20 in TBS) (GAR/Ig Nordic Pharmaceuticals and Diagnostics), and subsequently washed with TBS. Thereafter the grids were placed for 30 min on a drop of TBS containing a 1/50 dilution of the PAP complex and 1% goat serum, and subsequently washed. This was followed by the reaction with 3,3'-diaminobenzidine (DAB) for 7 min, staining with osmium tetroxide 2% on 0.05 M veronal acetate, washing with veronal acetate and drying. The reaction with DAB was carried out according to Weir *et al.*¹¹. Note the accumulation of darkly stained PAP complexes on the microtubules and the diffuse layer of PAP complexes between them. *c*, Actin filaments polymerised *in vitro* according to the method of Carsten¹². The fibres were adsorbed on to nickel grids covered with Formvar, fixed with glutaraldehyde and stained with the PAP method using the antibody dilution, in an identical fashion as described for *b*. Note the complete absence of PAP complexes from the filaments. *d*, Microtubules polymerised *in vitro* and stained with the PAP method as described above with omission of the antibody solution II. Note the complete absence of PAP complexes from the microtubules and from the spaces between them. The enlargement of the microtubules (± 35 nm instead of ± 24 nm) is probably due to the rehydration and the coating with normal goat serum. *e*, Part of *b* enlarged to the same magnification as *f*. Untransformed mouse embryonal cell in culture (MO)¹³ stained with the PAP-technique. Cells, grown on cover slips, were fixed in 0.25% glutaraldehyde in 0.1 M sodium cacodylate pH 7.4, for 5 min. After washing in the same buffer (30 min), they were postfixed with a series of acetone 50% \rightarrow 100% \rightarrow 50% at 4°C; and placed in TBS for 15 min; brief washing in TBS; 1/800 antibody dilution (no. II, Table 1) in TBS \times 1% normal goat serum, 30 min; extensive washing as before; 1/20 GAR, 30 min; extensive washing as before; 1/300 PAP in TBS containing 1% normal goat serum, 30 min; extensive washing in TBS. The reaction with DAB was the same as in Fig. 1b. The reaction product was stained with osmium tetroxide (2% in veronal acetate) for 10 min at 4°C. After washing, the cover slips were mounted in Fluormount with the cells downwards. Note the dense cytoplasmic network and the absence of nuclear staining, except for pronounced staining of the nuclear membrane ($\times 500$).

individual microtubules appear as heavily stained arrays of PAP complexes with a diameter of ± 100 nm. This size can be expected in view of the diameter of microtubules (± 24 nm), and of the PAP complex (± 20 nm) linked to the microtubules by a double layer of immunoglobulins. Because of this enlargement the labelled microtubules are clearly visible when the grids are examined with the light microscope. Fixation with formaldehyde (3.5%; 5 min) results in a distortion of the microtubules and a loss of the protofilamentous substructure at the ultrastructural level. But these structures still bind the immune complex. After glutaraldehyde or formaldehyde fixation PAP complexes are evenly distributed in the open spaces between the microtubules (Fig. 1b). The staining pattern is identical when microtubules are polymerised directly from a 100,000g supernatant from homogenised rat or rabbit brain⁸ or when microtubules are prepared from a tubulin solution that is enriched by two polymerisation-depolymerisation steps⁹.

Table 1 Results obtained with different antibody solutions and different substrates

Substrate	Antibody solution	Dilution	Staining
Microtubules	II purified γ -G	1/800–1/50,000	+
	Immune rabbit serum	1/100,000	—
Microtubules	I γ -G	1/800–1/6,400	+
	Immune rabbit serum	1/12,500	—
Actin	I	1/3,200	—
Collagen	I	1/3,200	—
Microtubules	III	1/800–1/3,200	+
	Antiserum against purified tubulin		
Microtubules	IV RAB/Alb	1/800	—
Microtubules	V adsorbed γ -G normal rabbit serum	1/800	—

Antibody solution I was prepared by injecting rat brain tubulin, purified by two polymerisation-depolymerisation steps⁹, homogenised with Freund's complete adjuvant. The immunoglobulin serum fraction was obtained by two precipitations with sodium sulphate. The protein concentration was 36.6 mg ml⁻¹. Antibody solution II was derived from solution I through further purification by affinity chromatography on Sepharose-4B to which the antigen was coupled. The protein concentration was 5 mg ml⁻¹. Antibody solution III is a crude antiserum raised against SDS-gel purified tubulin. Antibody solution IV is a rabbit anti-bovine serum albumin antiserum (RAB/Alb Nordic Pharmaceuticals and Diagnostics, Antwerp, Belgium). Antibody solution V is an immunoglobulin G fraction from normal rabbit serum adsorbed on to a column containing Sepharose-4B to which tubulin was coupled. The protein concentration was 15 mg ml⁻¹.

When rabbit muscle actin filaments, or rat skin collagen fibres¹⁰, polymerised *in vitro*, are subjected to an identical procedure, they remain completely unstained (Fig. 1c). Neither is any background visible, as is the case with formvar-coated grids that were not covered with any protein. Microtubule staining is also completely absent if one or more of the immune reagents is omitted (Fig. 1d). When rabbit anti-bovine serum albumin IgG or purified rabbit γ -globulins, previously absorbed on to a column of Sepharose 4B to which tubulin was coupled, are used the microtubules are not stained. Neither is any background staining visible. The results that were obtained with various antibody solutions on different substrates are given in Table 1.

Preliminary results, using the fixation procedure of Brinkley *et al.*⁴ but the PAP method instead of immunofluorescence showed that a fine cytoplasmic network and the mitotic spindle can be visualised in cultured cells at the light microscopic level. This resembles the immunofluorescent picture in all respects. Moreover, a similar network is visible after fixation with glutaraldehyde (Fig. 1f). The network seems to consist of more individual lines that have a greater definition than after formaldehyde fixation. Finally, semithin

(1 μ m) and thin sections (0.07 μ m) can be made of the same cells after embedding them in Epon.

In semithin sections the cytoplasmic network is visible either sectioned longitudinally or transversely.

At the ultrastructural level, both cytoplasmic and mitotic spindle microtubules are seen to be covered with stained PAP complexes, that are filling the clear zone normally present around them.

The cytoplasm contains evenly distributed PAP complexes. The mitochondria, the lumen of the endoplasmic reticulum, Golgi cisternae and vacuoles, and the bundles of microfilaments are completely unstained. The nuclear periphery, with the exception of the pores, shows pronounced staining. The nuclear content is negative. These preliminary observations are, however, subject to further investigation.

In conclusion, we have shown that it is possible to stain microtubules and most probably microtubular proteins in other configurations, with the PAP method using antibodies against purified rat brain tubulin. This method does not stain other fibrillar proteins such as actin or collagen.

This method is applicable at the light microscopic and ultrastructural level and provides a way of exploring the distribution of microtubules, tubulin and associated proteins and their interaction with other cellular components.

We thank Dr A. D. Strosberg for discussions and for reading the manuscript, G. Van Nijen, R. Van Ginckel and C. Jonckheere for technical assistance, L. Leyssen for photography and M. Van de Ven for typing the manuscript. Barbiturate reversal of amino acid antagonism produced by convulsant agents

THE hypnotic and anticonvulsant properties of pentobarbitone and related barbiturates may be closely associated with the actions of γ -aminobutyric acid (GABA)¹⁻³, an inhibitory transmitter at both pre- and postsynaptic receptors in the mammalian central nervous system⁴. Pentobarbitone prolongs pre-⁵ and postsynaptic³ inhibition as well as hyperpolarising central neurones^{2,3}. Although it has been suggested that pentobarbitone prolongs synaptic inhibition by delaying the removal of GABA from the synaptic cleft^{3,6} a direct action of pentobarbitone on GABA receptors cannot be excluded². We have explored this possibility both in the rat isolated sympathetic superior cervical ganglia preparation, which possesses GABA receptors analogous to those in the mammalian brain⁷, and *in vivo* on single neurones in the rat brainstem. In these experiments pentobarbitone, in amounts which produced no apparent GABA-mimetic effects, reversed the actions of bicuculline methochloride (BMC), a selective GABA antagonist.

Ganglia were isolated from Wistar rats under urethane anaesthesia and desheathed before superfusion with Krebs' solution (containing 2.6 μ M hyoscine) as described previously⁸. Surface potentials were monitored continuously through Ag⁺/AgCl electrodes in contact with the ganglion body and postganglionic trunk and connected across a Servoscribe 1-s potentiometric recorder.

The addition of GABA, at concentrations greater than 1 μ M, to the solution superfusing the ganglia produced a dose-dependent depolarisation. Pentobarbitone also depolarised ganglia but only at much higher concentrations. The threshold concentration was in excess of 80 μ M. Responses to pentobarbitone were less susceptible to the effects of BMC than were responses to equally effective doses of GABA.

Application of pentobarbitone during superfusion with BMC reversed the action of this GABA antagonist. An example of this reversal is shown in Fig. 1. Responses to GABA (30 μ M) were reduced approximately 50% in the presence of BMC (14 μ M). Addition of pentobarbitone in increasing concentrations reversed the effect of BMC. At this concentration of BMC the maximum reversal occurred generally at 80 μ M pentobarbitone. The effect of pentobarbitone was rapid in the onset, as well as offset; within 20 min following its removal responses to GABA were again reduced to the original antagonised level.

Pentobarbitone (80 μ M) applied in the absence of BMC (Fig. 1) generally did not produce responses to GABA administered at concentrations up to 30 μ M. But responses to larger concentrations of GABA were always markedly reduced. In spite of this, responses obtained to these concentrations of GABA, in the presence of both pentobarbitone and BMC, were always greater than in the presence of either substance alone.

The antagonism of responses to GABA produced by other substances, picrotoxin, tetramethylenedisulphotetramine and isopropyl bicyclopophosphate was also reversed by pentobarbitone whereas the antagonism of depolarising responses to carbachol (33 μ M), produced by hexamethonium (75 μ M), was not. In addition the non-selective depression of responses to GABA produced by strychnine⁷ (73 μ M) was reversed by pentobarbitone but the similar depression of responses to carbachol, produced by the same concentration of strychnine, was not reversed.

Other barbiturates also reversed the effects of the BMC. However, of those so far tested, only quinalbarbitone was found to be more potent (2-3 times) than pentobarbitone. The isomer of pentobarbitone, amylobarbitone, and the sulphur derivative thiopentone had similar activity to pentobarbitone whereas phenobarbitone was about 5% the potency.

This investigation was extended to *in vivo* experiments

Fig. 1 Reversal by pentobarbitone of the antagonism of depolarising responses to GABA produced by bicuculline methochloride in an isolated superior cervical ganglion of the rat. The ganglion was superfused with Krebs' solution at 1 ml min⁻¹ and the surface potential measured as described previously^{7,8}. GABA (30 μ M) was applied for 1-min periods, indicated by the solid bars below the record, at intervals of 13 min. The recorder paper drive was switched off in between responses for periods of approximately 8 min (gaps in record). Pentobarbitone (PB, 4-120 μ M) and bicuculline methochloride (14 μ M) were present in the superfusing solution during the periods shown. Note that (1) pentobarbitone (80 μ M) applied in the absence of bicuculline methochloride neither depolarised the ganglion nor markedly altered responses to GABA, and that (2) increasing concentrations of pentobarbitone reversed the depression of responses to GABA produced by bicuculline methochloride.

performed on six adult albino rats (200–250 g) anaesthetised with intraperitoneal urethane (1.4 g kg^{-1}) and prepared for brainstem recording by the method of Bradley and Dray⁹.

Multibarrelled glass micropipettes were used to record extracellular action potentials from single spontaneously active neurones in the medulla and to administer substances close to them by electrophoresis. Micropipettes were filled immediately before use by a glass-fibre method or by centrifugation. The recording barrel contained 3 M sodium chloride. Another barrel containing 1 M sodium chloride was used to balance the net current at the electrode tip to 0 or to test for electrophoretic current effects. Other barrels contained freshly prepared solutions of GABA,

kg^{-1} , four cells). Pentobarbitone also reversed the non-specific antagonism of glycine by BMC on every occasion. The effects of pentobarbitone were never accompanied by significant changes in background firing and the antagonism of GABA by BMC was rapidly restored after the end of the pentobarbitone administration (Fig. 2). This antagonism of GABA could also be restored during a pentobarbitone administration by increasing the ejecting current of BMC.

Further tests with pentobarbitone alone, administered to the same neurones (six cells) on which a reversal of BMC antagonism had already been demonstrated, did not reveal any significant potentiation of submaximal responses to GABA or glycine. In fact, on occasions the responses to

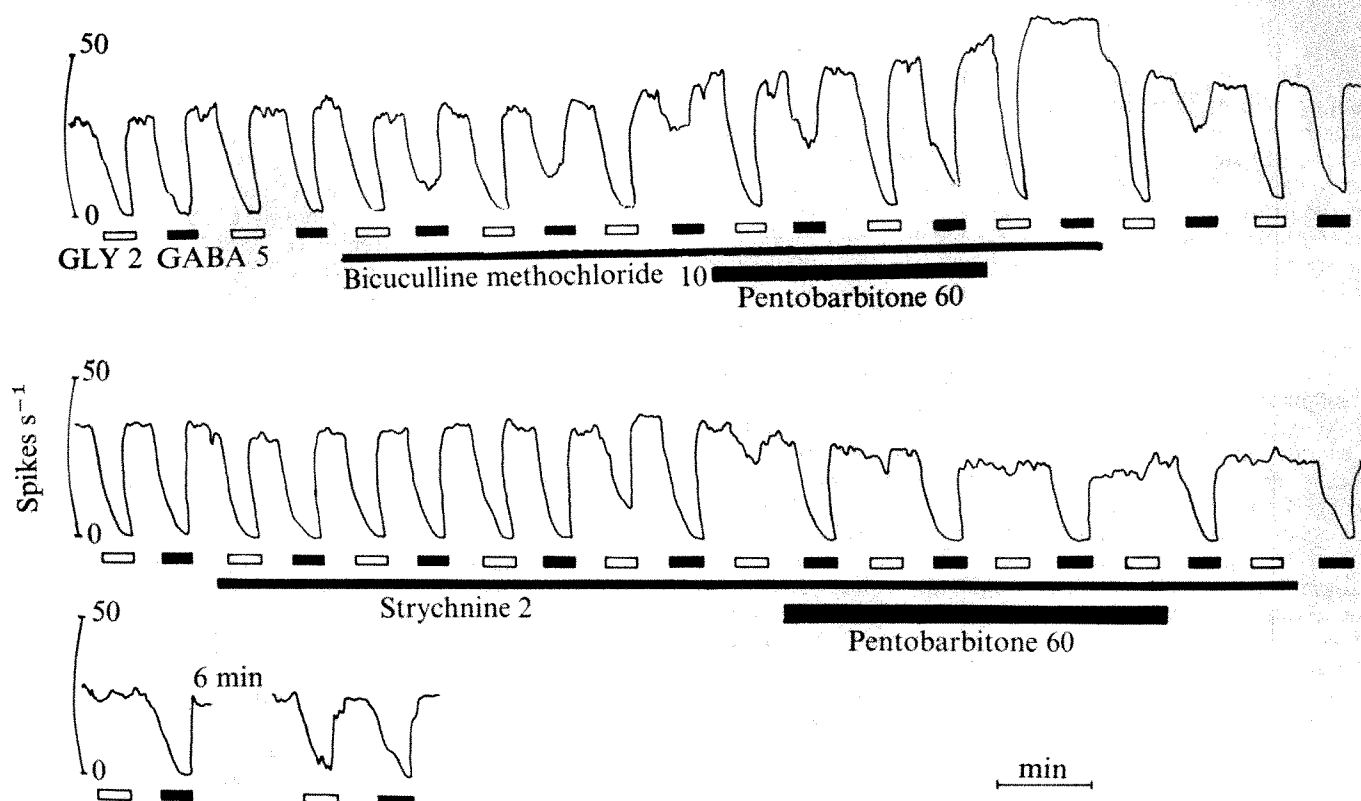

Fig. 2 Continuous ratemeter records of a spontaneously active neurone in the medulla showing the reversal by pentobarbitone of a selective antagonism of GABA by bicuculline methochloride. The GABA block by BMC was restored after the termination of the pentobarbitone administration. Strychnine selectively abolished the response to glycine on the same cell but this effect was not reversed by pentobarbitone. All expelling currents are indicated in nA.

0.2 M (pH 3.5); glycine, 0.2 M (pH 3.5); bicuculline methochloride, 5 mM (pH 3.5); strychnine, 5 mM (pH 3.5); pentobarbitone sodium, 20 mM (pH 9.5). Action potentials were recorded and displayed using conventional techniques.

Reproducible responses to GABA and glycine were obtained during consecutive applications of these compounds during a fixed time sequence. A continuous administration of BMC (10–20 nA) reduced the responses to GABA in all 19 neurones tested an example of which is shown in Fig. 2. In four of these cells responses to glycine were also partially reduced.

Pentobarbitone (40–80 nA, mean 56.6 nA; 1–6 min, mean 3.7 min) ejected from an adjacent barrel of the same micropipette during the continued administration of BMC partially or completely reversed the GABA antagonistic effect of BMC (Fig. 2). The reversal occurred in all neurones tested (26 tests on 19 neurones) and was also seen following intravenous administration of thiopentone (1 mg

GABA and glycine were reduced by the same current of pentobarbitone previously shown to reverse the antagonism produced by BMC. Larger currents ($>100 \text{ nA}$) of pentobarbitone produced marked depression of spontaneous firing.

Strychnine (2–5 nA) reversibly reduced the effects of glycine on 13 neurones and with larger ejecting currents (10–15 nA) additional reduction of the responses to GABA was observed (two cells). All tests with strychnine were performed on neurones which had also been tested before with BMC. The additional administration of pentobarbitone (30–70 nA; mean 64 nA; 2–13 min, mean 5.8 min) during a partial (50%) or complete suppression of glycine by strychnine, reversed strychnine antagonism in only five neurones. In most neurones strychnine antagonism of glycine was not affected although the amounts of pentobarbitone were in excess of those which had reversed BMC antagonism of GABA on the same cells. On the two cells where a non-

selective strychnine antagonism of GABA was observed, pentobarbitone readily and reversibly restored the GABA responses.

At present it is difficult to understand the mechanism by which barbiturates reverse the effect of BMC or other GABA antagonists. It might be argued that the inhibition of GABA uptake produced by pentobarbitone *in vitro*⁶ could account for the reversal. Uptake inhibition would increase the concentration of GABA in the vicinity of the receptors which might then overcome the competitive antagonism produced by BMC. But, uptake inhibition would also be expected to potentiate the responses to GABA even in the absence of BMC (compare the potentiating effect of nipecotic acid—ref. 10). However, no potentiation of responses to GABA was observed when pentobarbitone was administered in amounts which were subsequently shown to reverse the effect of BMC. In addition the presence of 3 mM nipecotic acid, which reduced ganglionic uptake of ³H-GABA (0.1 μ M) by more than 90%, did not affect the ability of pentobarbitone to reverse the action of BMC. An alternative explanation might be that GABA and BMC bind to the cell surface at different sites. If BMC binds at a site adjacent to the GABA site such that, when present, it prevents access of GABA to the receptor not because of preferential binding to the receptor but by either occluding it, or by distorting it. If pentobarbitone has an affinity for the antagonist binding site it could displace the BMC without itself affecting the receptor. GABA could then regain access to the receptor.

The possibility of a difference in agonist and antagonist binding sites is not without precedent. Snyder and Young¹¹⁻¹³ have suggested that glycine and strychnine bind to two separate but mutually interacting sites on synaptic membrane preparations of spinal cord and brainstem. They suggest that the antagonist binding site may, in fact, be associated with the ionic conductance mechanism for chloride whereas the agonist, glycine, interacts with the glycine recognition site. Snyder and his group¹⁴ have also demonstrated GABA receptor binding in similar preparations. However, as yet there is no evidence of separate binding sites for BMC and GABA. Interestingly, in this same study it was shown that pentobarbitone does not affect GABA binding. It remains to be seen whether pentobarbitone affects the binding of BMC in the same preparation.

The barbiturates are particularly useful in the treatment of convulsant poisoning^{15,16}. The present observations suggest that this action may be related to an effect at sites associated with inhibitory amino acid receptors.

We would like to thank Alan Hudson for helping with some of these experiments.

Digynic triploidy after superovulation in mice

SUPOVULATION through the administration of exogenous gonadotropins¹ has been widely used in mice for experimental purposes, and cytogenetic evidence has shown^{2,4} that the technique does not affect adversely the chromosome constitution of either released ova or zygotes. We have noticed, however, that the incidence of triploidy increased considerably among zygotes obtained through superovulation followed by natural mating in adult A-strain mice⁵. We have therefore investigated the origin of the extra genome in such embryos.

Six- to 8-week-old A/He females received 10 IU of pregnant mare serum (PMS, Schering) at 16.00 h and 10 IU of human chorionic gonadotropin (HCG, Schering) 44 h later. They were allowed to mate with CBA-T₆T₆ males after the second injection. Spontaneously ovulating and mated females served as controls. Eggs at the pronuclear stage were flushed from the oviduct early in the afternoon of the day when a copulation plug was found. Postimplantation embryos were dissected at 7.5 d of gestation from superovulated females, and at 6.5 or 7.5 d from control females. By changing the interval between HCG injection and death, we recovered preimplantation embryos from the eight-cell to the late blastocyst stage.

Totals of 430 and 1,423 viable embryos were obtained from 20 superovulated and 129 control females. Chromosomes were analysed in 421 and 1,406 cases, respectively (Table 1). Failure in nine and 17 embryos was due either to accidental loss of specimens or to the absence of metaphase cells. The frequency of diploid embryos was significantly lower in the superovulated than in the control group, the difference being ascribed to the fivefold increase in the incidence of digynic triploidy (Fig. 1). The frequency distribution of the two possible sex chromosome complements in digynic triploidy was 22XXX:25XXY:5? in the control and 30XXX:45XXY:6? in the superovulated group. The ratio in diandric triploidy was 4XXX:6XXY:1XYY in the control and 1XXY:1XYY in the experimental group, implying apparently reduced viability of XYY zygotes, as suggested in man⁶. Except for this specific class, digynic and diandric embryos, being chromosomally balanced, seemed to be of equal viability. It is, however, possible that more diandric eggs were lost early in development than digynic eggs, if dispermy occurred primarily in deteriorating oocytes. The incidence of triploidy (4.5%) in the control group was nearly comparable with that obtained in 'silver' mice. The high incidence was not ascribed to the interstrain cross¹⁰, for the situation was not appreciably different when strain A males were used. (N.T., unpublished results.)

The increase in digyny after superovulation would be due to suppression of either the first or the second polar body unless exogenous gonadotropins preferentially stimulated tetraploid oocytes. The nature of the polar bodies, and the number and relative size of the pronuclei¹¹, could reveal a disturbance at maturation division, an error at fertilisation or both. Only a small proportion of activated eggs had the first polar body in our preparation, which agrees with previous findings¹¹. Moreover, about one-tenth of the zygotes with a large (male) and a small (female) pronucleus possessed neither the first nor the second polar body. Inasmuch as these usually had excessively flattened cytoplasm, a loss

of the second polar body during preparation probably explains most of them. The two pronuclei were similar in size in a proportion of eggs from the control and the experimental group. Although variability in pronuclear size might account for most of such eggs, diploidy of the female pronucleus could not be ruled out.

Fig. 1 Triploid metaphases from 7.5-d embryos dissected from A/He females mated with CBA-T₆T₆ males. *a*, Digynic triploidy with a single T₆ marker (arrow) and XXX sex chromosome constitution. *b*, Diandric triploidy with two T₆ markers (arrows) and XYY sex chromosome complex. Dissected embryos were incubated in Eagle's medium supplemented with foetal calf serum (20%) and Colcemid (0.1 µg ml⁻¹) for 2 h. Chromosome preparations were made according to the method of Wroblewska and Dyban⁶ with modifications⁷.

A total of 354 of 1,264 superovulated eggs had three pronuclei. Digyny was presumed to occur in 333 and 254 eggs on the basis of the absence of the second polar body and the difference in pronuclear size, respectively. There were 21 diandric (dispermic) eggs estimated on the basis of the retained second polar body, and 49 on the basis of pronuclear size (Fig. 2). Divergence between the two estimates in both classes of eggs may diminish considerably if loss of the second polar body and the variability in pronuclear size are taken into account. The interpretation of our data may be that (1) most triploid embryos identified in later stages derive from zygotes with three pronuclei; (2) digyny outnumbers diandry, and (3) disturbance of the second maturation division is the major cause of digyny. All of the zygotes with three pronuclei found in the control mating were compatible with suppression of the second polar body. Eight zygotes with four pronuclei presumably represented dispermic eggs whose second polar body was suppressed.

Fig. 2 Presumptive triploid zygotes at the pronuclear stage. Two small (female) pronuclei with a single nucleolus in (*a*) suggest digyny due to suppression of the second polar body, and two large (male) pronuclei with several nucleoli in (*b*) suggest dispermic. Possibly the second polar body was lost during preparation.

Table 1 Chromosome findings in 6.5–7.5-d embryos from control and superovulated females mated with CBA-T₆T₆ males

† $P \leq 0.005$.

The proportion of informative embryos was low at the morula–blastocyst stage because of technical difficulties. We obtained 1,022 informative cases including 219 triploids. As diagnosis of aneuploidy was difficult at this stage, embryos with 38–41 chromosomes were classified as diploid. The incidence of diploid, triploid and tetraploid embryos at pronuclear, morula–blastocyst, and postimplantation stages are compared in Table 2. To make data comparable, genuine diploids, aneuploids and mosaics in the diploid range were combined as a diploid class, and a single 2n/3n mosaic blastocyst was included in a triploid class. No difference was found in the three classes of embryos between the morula–blastocyst and the postimplantation stage, but triploidy was

numbers according to Edwards' formula¹². As Table 3 shows, the ratio between cleavage numbers of triploids and those of diploid sibs was nearly constant, ranging from 0.88 to 0.92 for the stages examined. This may imply that the cell-cycle time was about 10% longer in triploids than in diploids. Extrapolation of this relationship predicts that the cell number of triploid embryos would become half that of diploid sibs at 10th cleavage (about 5.5 d) and a quarter at 20th cleavage (about 10.5 d), though delay might be accelerated after implantation. It should be mentioned, however, that there were substantial variations in developmental potential among individual triploid embryos^{2,13–15}.

Foetal development, investigated extensively in mice

significantly more frequent at the pronuclear stage. Consequently we conclude that a proportion of triploid zygotes was lost in early cleavage stages. Remaining triploids seemed to survive implantation.

The developmental characteristics of triploids before implantation were assessed as follows. Litters were classified into groups according to the average cell numbers of diploid sibs. Average cell numbers were converted into cleavage

after induced ovulation, has revealed substantial mortality during cleavage, about the time of implantation, at mid-pregnancy and at parturition^{16–18}. The extent to which chromosome imbalances is causally related to embryonic mortality has not been explored yet. Our observation strongly suggests that digynic triploids constitute an appreciable proportion of pre- and postimplantation losses. Possibly the same holds for mice of other strains, even if

the frequency of triploids is less pronounced than in the strain we used. This assumption is supported by two lines of evidence. These are (1) high incidence of chromosome abnormalities, including triploidy, in rabbit blastocysts obtained through superovulation by PMS¹⁹, and (2) the increased frequency of triploidy and other types of chromosome anomalies observed in human spontaneous abortuses after ovulation-inducing therapy by HMG and HCG, clomiphene citrate and HCG, or HCG alone²⁰.

Selective inhibition of neuronal GABA uptake by *cis*-1,3-aminocyclohexane carboxylic acid

It is now generally accepted that GABA is an important inhibitory synaptic transmitter in the vertebrate central nervous system. However, there remain many problems in elucidating the precise roles of GABA in the brain. One important problem is the existence of a glial pool of GABA which makes it difficult to determine the origin of GABA released during experiments designed to demonstrate the release of GABA after nervous stimulation. It was thought at one time that this problem might be overcome by utilising the uptake processes for GABA to label the neuronal GABA pools, with for example, ³H-GABA. However, it is now clear that in many areas of the brain, GABA is also taken up by glial cells and in some areas, this glial uptake may actually predominate. The transport processes for GABA in neurones and glia have remarkably similar properties but do appear to have slightly different structural requirements.

In the present study, we have found that a conformationally restricted structural analogue of GABA, *cis*-1,3-aminocyclohexane carboxylic acid (ACHC) (Fig. 1), which has previously been reported to competitively inhibit GABA transport in slices of cerebral cortex¹, selectively inhibits neuronal transport of GABA and has little or no effect on transport of GABA into glial cells. This selective inhibition was revealed by studying the uptake of ³H-GABA by isolated slices of rat cerebral cortex, frog retinae, rat retinae and rat sympathetic ganglia. Autoradiographic studies with ³H-GABA have shown a predominantly neuronal uptake in

Fig. 1 Chemical line diagrams for nipecotic acid ((±)-piperidine-3-carboxylic acid) (a), ((±)-*cis*-3-aminocyclohexane carboxylic acid) (b), 4-aminotetrotic acid (4-aminobut-2-ynoic acid) (c).

cortical slices¹ and frog retinae³ and a glial uptake in rat retinae⁴ and ganglia⁵.

The effects of ACHC on ³H-GABA uptake by these tissues are summarised in Table 1. It can be seen that the uptake of ³H-GABA (0.1 μM) by cortical slices and frog retinae was 50% inhibited (IC₅₀) by ACHC at a concentration of 62 μM and 960 μM respectively but uptake into rat retinae and ganglia was unaffected by ACHC at a concentration of 1 mM. Since this concentration of ACHC was approximately 100 times the apparent K_m of the high-affinity GABA transport processes, these results indicate that ACHC has no significant inhibitory effect on GABA transport in glia of the rat retina and ganglion.

To study further the selectivity of ACHC on neuronal and glial systems, its ability to stimulate ³H-GABA release was investigated. In these experiments the tissue was pre-loaded with ³H-GABA and then superfused in a small chamber with medium containing aminooxyacetic acid (0.1 mM) to prevent catabolism of the accumulated ³H-GABA. During the superfusion the tissue was exposed for 4- or 6-min periods to medium containing ACHC or non-radioactive GABA. ACHC caused an increase in the efflux of ³H-GABA from superfused cortical slices and frog retinae (Fig. 2). This effect of ACHC was concentration dependent. Thus, in both tissues ACHC (10 μM) produced an approximately twofold increase in the efflux rate coefficient and this was increased further to about fivefold at a concentration of ACHC of 100 μM (cortex 5.2 ± 0.21, frog retina 4.5 ± 0.16, mean ± s.e.m. of six experiments). At 1 mM ACHC, much larger effects were seen, the rate coefficients increasing more than 14-fold (cortex 14.9 ± 1.21, retina 14.1 ± 2.01, mean ± s.e.m. 3-6 experiments). In contrast to the above tissues in which neuronal uptake of GABA predominates, the efflux of ³H-GABA from glial cells of the rat retina and ganglion was virtually unaffected by ACHC at concentrations up to 1 mM although GABA

Fig. 2 Effect of GABA (G) and ACHC (A) on the rate of ^3H -GABA efflux from cerebral cortex slices (a), frog retina (b), rat retina (c), and rat sympathetic ganglion (d). Tissues were given a preliminary incubation for 10 min in 5 ml Krebs' bicarbonate solution at 25 °C. ^3H -GABA was then added (final concentration 1 μM) and the incubation continued for 30 min (ganglia 2 h). The tissue was then transferred to a superfusion chamber (volume 1.0 ml). Four slices of cortex (0.25 mm thick) or two retinæ were placed in each chamber and superfused at 25 °C with oxygenated medium at a rate of 1 ml min⁻¹. Fractions (2-ml) were collected and the radioactivity determined by liquid scintillation counting. The efflux of ^3H -GABA from sympathetic ganglia was measured as described previously¹⁴: ganglia were superfused with medium at 0.5 ml min⁻¹, and the radioactivity in 2-min samples determined. The results are expressed as the fractional rate coefficient defined as the amount of radioactivity collected during a 2-min period divided by the arithmetic mean of the total radioactivity present in the tissue at the beginning and end of the same collection period. All media contained the GABA transaminase inhibitor, amino-oxyacetic acid, 100 μM (ganglia 10 μM), as previous experiments have shown that in the presence of this inhibitor the radioactivity accumulated and released by these tissues corresponds to > 95% ^3H -GABA (refs 14 and 20-22).

(1 mM) itself produced large increases in the efflux of ^3H -GABA from all four tissues (Fig. 2).

The stimulated efflux of ^3H -GABA produced by ACHC and by GABA itself was dependent on the presence of Na⁺ ions in the medium. In the absence of Na⁺, the spontaneous release from the tissue was increased sixfold but the addition of GABA (1 mM) or ACHC (1 mM) did not cause any additional release of ^3H -GABA (Fig. 3). These effects were not due to damage of the tissue because when the Na⁺ level was restored, a stimulated efflux of ^3H -GABA was obtained with both GABA and ACHC (Fig. 3). These results suggest that the increased efflux of ^3H -GABA produced by ACHC (and GABA) is due to inhibition of the GABA transport process which is presumably

'recapturing' a large proportion of the spontaneously released ^3H -GABA. The alternative possibility that the stimulated release of ^3H -GABA is due to a coupled exchange process⁶ with the ACHC or exogenous GABA is unlikely since in the absence of sodium ions GABA uptake is prevented and this would be expected to reduce the spontaneous GABA efflux rather than cause the marked increase that was found in the present experiments.

The above experiments indicate that (in the tissues studied) ACHC is a selective inhibitor of neuronal GABA transport and is capable of producing a net increase in the efflux of GABA from neuronal but not glial GABA pools. The properties of ACHC which confer this specificity are of interest. In aqueous solution ACHC is likely to exist as the zwitterionic form and from *pK* measurements it has been concluded that the molecule exists predominantly in the diequatorial conformation⁷. In this conformation the compound represents a partially restricted, partially folded analogue of GABA where the separation of zwitterionic centres (mean of the two N...O distances) is approximately 5.6 Å. The corresponding distance observed in the crystal structure of β -alanine is approximately 3.8 Å (ref. 8). Since β -alanine seems mainly to inhibit glial uptake of GABA⁹, the selectivity of inhibitors of GABA uptake is probably related to the separation of their zwitterionic

Table 1 Effect of ACHC and other analogues on GABA uptake

Analogue	IC ₅₀ (Concentration of compound that inhibits uptake of GABA 0.1 μM by 50%)			
	'Neuronal uptake'		'Glial uptake'	
	Cortical slices	Frog retina	Rat retina	Sympathetic ganglia
<i>cis</i> -1,3-aminocyclohexane carboxylic acid	62 μM	960 μM	No effect at 1 mM	No effect at 1 mM
4-Aminotetrollic acid	330 μM	Not tested	No effect at 1 mM	No effect at 1 mM (ref. 15)
Nipecotic acid	12 μM	1 mM	640 μM	200 μM
2,4-Diaminobutyric acid	66 μM (ref. 16)	Not tested	58 μM (ref. 17)	No effect at 1 mM (ref. 10)
β -alanine	21 mM (ref. 9)	Not tested	390 μM (ref. 18)	59 μM (ref. 14)

Slices (0.1 × 0.1 × 0.2 mm) of cerebral cortex (10 mg)¹⁹ or individual retinæ (10 mg)¹⁷ were preincubated with analogue for 10 min at 25 °C in 5 ml Krebs' bicarbonate medium. ^3H -GABA was then added to give a final concentration of 0.1 μM and the incubation continued for 10 min. Desheathed ganglia¹⁰ were incubated in Krebs' solution at 25 °C for 30 min with ^3H -GABA (0.1 μM) in the absence or presence of analogue. The tissue was then recovered, washed with fresh medium at 25 °C, and transferred to counting vials. The radioactivity was extracted by dissolving the tissue in Soluene-350 (Packard) and measured by liquid scintillation counting. The counts were corrected for efficiency by the channel ratio method. The inhibition of ^3H -GABA uptake produced by 3 or 4 concentrations of each analogue was measured and used to obtain the IC₅₀ value¹⁸. The value at each concentration of analogue was the mean of 3-6 results and the s.e.m.s were less than 10%.

Fig. 3 Effect of Na^+ ions on the stimulated release of ^3H -GABA from cortical slices produced by ACHC (1 mM) and GABA (1 mM). Experimental details were as described in Fig. 2 except that a Tris-HCl buffered medium was used and where indicated the Na^+ in the medium was replaced with sucrose. The top panel shows that the stimulated release of ^3H -GABA produced by GABA (G) and ACHC (A) was abolished by exposure of the tissue to Na^+ free medium (indicated by the solid bar). This lack of response was not due to tissue damage because the stimulated release of ^3H -GABA was restored when the Na^+ -free medium was replaced with normal medium (bottom panel). Note also the increased spontaneous efflux of ^3H -GABA in the absence of Na^+ ions.

centres. The upper limit of this separation for interaction at glial uptake sites is apparently lower than at neuronal uptake sites. This is supported by the fact that 4-aminotetrolic acid (4ATA), where the zwitterionic centres have a minimum separation of 5.5 Å was also found to be a selective neuronal inhibitor of GABA uptake (Table 1). In contrast, nipecotic acid, which like ACHC, also adopts the chair conformation in both the solid state and aqueous solution but has a smaller separation of charged centres of approximately 4.5 Å, interacts with both neuronal and glial transport sites for GABA (Table 1).

2,4-Diaminobutyric acid (DABA) has previously been suggested as a selective inhibitor of neuronal GABA transport because it inhibits uptake by cortical slices but not by sensory⁹ and sympathetic ganglia¹⁰. However, DABA is almost equally potent in inhibiting GABA uptake in rat retina and cortical slices. This lack of selectivity is presumably due to the greater flexibility of this molecule.

In addition to its affinity for neuronal GABA transport sites, ACHC has been shown to have an inhibitory effect on the firing of central neurones. This effect is presumably mediated by GABA receptors since it is blocked by the GABA antagonist, bicuculline¹¹ (M. A. Simmonds and F. Andres-Trelles, personal communication). In contrast, we found that ACHC (3 mM) had no effect on ganglionic GABA receptors since it failed to produce the neuronal depolarising response characteristic of GABA itself¹² (Fig. 4). Nipecotic acid (3 mM) also had no effect on ganglionic neurones but depolarising responses were produced by relatively high concentrations of DABA (3 mM) and β -aminobutyric acid (BABA) (3 mM) (Fig. 4).

When the ganglionic glial cells were allowed to accumulate GABA by superfusion of the ganglion with 1 mM GABA for 1 h (ref. 14), it was found that the depolarisations produced by DABA and BABA were potentiated and

nipecotic acid, which was previously without effect, now produced a prolonged depolarisation. In contrast, ACHC still did not depolarise the ganglionic neurones (Fig. 4). The potentiation of the depolarising responses of DABA and BABA after loading of the glial cells with GABA is due to their affinity for the glial transport sites. These compounds inhibit the reuptake of GABA and so increase the net release of GABA from the glial cells as illustrated previously (Fig. 2). This indirect activation of ganglionic GABA receptors is even more strikingly demonstrated in the case of nipecotic acid which produced no depolarisation at all until after the glial cells were loaded with GABA but then produced a prolonged depolarisation of the ganglionic neurones (Fig. 4). Unlike nipecotic acid, ACHC did not depolarise ganglionic neurones after the glia were loaded with GABA. This failure to show an indirect effect on ganglionic GABA receptors is consistent with this compound's lack of affinity for glial uptake sites. However, since

Fig. 4 Depolarising responses of an isolated superior cervical ganglion to GABA (G, 3 μM), ACHC (A, 3 mM), β -aminobutyric acid (B, 3 mM), 2,4-diaminobutyric acid (D, 3 mM) and nipecotic acid (N, 3 mM). The ganglion was obtained from a Wistar rat under urethane anaesthesia and desheathed before superfusion with Krebs' solution (1 ml min⁻¹) at 25 °C. Two non-polarisable Ag^+/AgCl electrodes were placed in contact with the postganglionic trunk and ganglion body and connected across a Servoscribe 1-s potentiometric recorder¹³. Responses correspond to an increase in the potential difference measured across these electrodes. Responses were obtained before (a) and after (b) superfusion of the ganglion with 1 mM GABA for 60 min followed by a further 60 min superfusion with Krebs' solution¹⁴. Each drug was in contact with the tissue for 4 min, indicated by the solid bars below the record, and was applied at intervals of 15–20 min (gaps between records). Aminooxyacetic acid (10 μM) was present in all solutions. Note that in b responses to nipecotic acid, β -aminobutyric acid and 2,4-diaminobutyric acid were larger than in a, whereas ACHC still failed to evoke a response.

ACHC does have affinity for neuronal GABA transport sites, this raises the interesting possibility that the inhibitory effects of this compound (and perhaps nipecotic acid) on the firing of central neurones is mediated indirectly by increasing the net efflux of endogenous GABA from neuronal pools. An alternative possibility which cannot be excluded at present is that the receptors for GABA on ganglia and on central neurones have different specificity requirements.

We are grateful to Mr C. Cooksey, University College, London, for the synthesis of ACHC and nipecotic acid and to Miss J. Gilroy, The School of Pharmacy, London, for

technical assistance. Part of this work was supported by grants from the MRC and the SKF Foundation to MJN.

Distribution of ions in a fluid-transporting epithelium determined by electron-probe X-ray microanalysis

STUDIES of fluid transport in epithelia have in general been limited to measurements of the composition of the transported fluid and the electrochemical gradients against which transport occurs¹⁻³. We have now used electron-probe X-ray microanalysis to measure the intracellular ionic concentrations. The data show that Na, K and Cl are not uniformly distributed within the cells; that the basal lamina is not entirely a passive membrane open to small ions, and that, in the particular epithelium studied, the stimulation of secretion greatly increases the intracellular Na concentration. In addition, the results do not support the standing gradient theory of fluid secretion.

Our technique (see legend to Fig. 1) is a refinement of that reported earlier⁴: tissue in known physiological condition is quench-frozen at -180°C , sectioned and transferred to the cold stage of an X-ray microanalyser. By the maintenance of low temperature, the water in the tissue is retained as ice and the distribution of soluble constituents is preserved—as has now been confirmed by experiments on several animal tissues (ref. 5, and our unpublished work). No chemical fixation or dehydration is used.

We studied the fluid-secreting upper portion of Malpighian tubules from the blood-sucking insect *Rhodnius prolixus*. Depending on the composition of the bathing medium, this epithelium secretes fluid rich in either Na or K or both⁶. Furthermore, the normally low rate of fluid secretion can be increased (up to 1,000 times) by treatment with diuretic hormone from the insect, or with 5-hydroxytryptamine (5-HT)^{7,8}.

Fig. 1 Scanning transmission electron micrograph of a deep-frozen hydrated section of the upper secretory portion of a Malpighian tubule from *Rhodnius prolixus*, showing two parts of a tubule, side by side, with various tissue components as labelled. Because of the wide range of contrast in the image, the basal lamina is not well shown in this micrograph. Tubules from unfed, fifth-instar *Rhodnius* were dissected in saline containing (mM) K^+ 20, Na^+ 132, Cl^- 160, Ca^{2+} 2, Mg^{2+} 9, H_2PO_4^- 4, HCO_3^- 10, glucose 34, together with 10–20% (w/v) dextran (molecular weight about 237,000). The dextran was included to reduce ice-crystal damage during quenching and to improve sectioning at low temperature; physiological experiments showed that it had no significant effect on secretion rates. For stimulated tubules, about 10^{-5} M 5-HT was added. (Other tubules from the same insect were isolated in identical saline containing ^{22}Na or ^{36}Cl , so that the concentrations of these ions in the secreted fluid could be measured for comparison with the microprobe results.) Lengths of tubules were mounted in a drop of dextran-saline on either silver or copper pins from a modified Cryokit attachment for the LKB Ultratome III (B. L. G. and N. G. F. Cooper, in preparation) or on small chunks for a cryomicrotome (SLEE Instrument Co.)⁴. They were then quench frozen at -180°C by plunging into Freon-13 (monochlorotrifluoromethane) maintained as a solid-liquid slush with liquid nitrogen, and transferred to the microtome. Sections (1–2 μm thick) were cut with steel knives at -80°C in the SLEE microtome, or with glass knives at -120° to -140°C in the LKB Cryokit. The sections were picked up on aluminium alloy collars covered with aluminised nylon films and loaded on to the low-temperature stage of a JEOL JXA-50A X-ray microanalyser. Special transfer devices were used to maintain the sections below -150°C to protect them from dehydration. Throughout the observations the specimen stage was kept at -170°C ; in these conditions the loss of mass from areas under the beam is unlikely to be significant^{1,26}. After each set of microanalyses the state of hydration of the section was checked as follows: the specimen holder was removed from the cold stage and held at the end of the loading rod within the column under high vacuum for 1–2 min. During this time the section warmed up and dried rapidly. The holder was then returned to the cold stage and analysis was repeated. From the change in X-ray continuum after drying, without parallel changes in either the characteristic counts or the distribution of elements, the section illustrated here and the other sections used for the results in Figs 2 and 3 were estimated to have retained 90–80% of their original water contents during the first analysis.

Figure 1 is a scanning transmission electron micrograph of a 1- μ m thick, deep-frozen, hydrated section of a *Rhodnius* Malpighian tubule stimulated with 5-HT and prepared as described in the legend. To analyse the distribution of elements, a focused electron beam about 100 nm in diameter was localised in different areas at magnifications of 5,000–20,000. Characteristic X-ray signals from the K α radiations of Na and K were recorded from diffracting spectrometers while a complete X-ray energy spectrum was obtained simultaneously from a Kevex Si(Li) detector. The energy spectrum provided data on K, Cl and other elements and on the continuum or "white" radiation used as a measure of local mass in the specimen⁹. After correction for background and for contributions to the mass counts from the substrate film and the specimen holder, each measurement was converted into an elemental mass fraction by comparison with the corresponding counts for known concentrations in dextran-saline in the same section^{9,10}. These values are given as mmol per kg wet weight of the areas indicated in Figs 2 and 3, which summarise the results of several experiments with both unstimulated and 5-HT-stimulated tubules. The salient results are as follows.

The fluid in the lumen of unstimulated tubules was different from the fluid secreted at a high rate by stimulated tubules. The former was much richer in potassium, much

poorer in sodium, and poorer in chlorine. It also contained a high concentration of phosphorus, presumably as inorganic phosphate.

In the cytosol the distribution of ions was non-uniform, but with respect to the main cell cytoplasm (areas 5 and 6 in Fig. 2), the only significant consequence of stimulation was an increase of about 30 mM in intracellular Na.

In the region of the brush border, our first analysis (areas 9–11 in Fig. 2) did not distinguish between the microvilli and the adjacent extracellular spaces; these data do not show a systematic variation in Na, K or Cl with distance into the lumen in the unstimulated tubules, but in the stimulated tubules the levels of all three ions increase towards the lumen. With more careful localisation of the probe (Fig. 3) we found significant differences between the microvilli and the extracellular spaces, and gradients along the length of both. In stimulated tubules, the increase of Na and K towards the lumen was particularly marked, so that both elements seemed to be significantly more concentrated towards the luminal end of the extracellular space than in the main lumen.

The basal lamina contained a higher concentration of K and lower concentrations of Na and Cl than the dextran-saline (Fig. 2, area 2). Phosphorus concentrations in the lamina were higher than elsewhere.

Fig. 2 Summary of microanalytical results obtained from stimulated and unstimulated Malpighian tubules of *Rhodnius*. The diagrammatic representation of the structure was prepared from conventional electron micrographs, and shows positions (but not actual sizes) of areas scanned by the probe. Measured concentrations of Na, K and Cl are expressed in mM (\pm 1 s.e.) per kg wet weight. The contents of the lumen in the unstimulated tubules also contained 20–30 mmol of phosphorus.

Our measurements on the fluid in the lumen confirm the validity of the technique. For stimulated tubules, the results for Na, K and Cl are in reasonable agreement with the findings of earlier physiological studies⁶. The fluid secreted by unstimulated *Rhodnius* tubules had not been analysed previously, but parallel isotopic measurements gave values of 50 mM for Na and 140 mM for Cl, again in good agreement. The unstimulated secretion is remarkably similar in composition to the product of the relatively slowly secreting Malpighian tubules of other insects, such as *Calliphora*^{8,11}.

The discovery of increased Na levels within the stimulated secretory cells should be considered together with the concurrent elevation of Na in the lumen. The finding is in accord with parallel measurements with ²²Na and ⁴²K, which show that in stimulated tubules the ionic composition of the secreted fluid is closely dependent on that within the cells (S.H.P.M., J. L. Wood and W. R. Harvey, in preparation). To further interpret the data we must take into account a special feature of the *Rhodnius* system: whereas the rate of fluid secretion by most insect Malpighian tubules depends strongly on the concentration of potassium ions in the bathing medium⁸, stimulated *Rhodnius* tubules can maintain high rates of secretion of Na-rich fluid in K-free media. All the available data seem to suggest that in *Rhodnius*, 5-HT (and presumably diuretic hormone *in vivo*) induces rapid entry of sodium ions into the tubule cells, and the elevation of intracellular Na is essential to a rapid secretion of sodium-rich fluid. (Similar mechanisms have been postulated for the action of hormones and neurotransmitters in several vertebrate epithelia¹²⁻¹⁶, although the

intracellular ionic changes have not been demonstrated conclusively in these tissues¹⁷.) One may postulate further that secretion is driven by an apical pump which transports Na and K in proportion to their availability.

In the brush border region, our measurements do not distinguish cleanly between microvilli and the channels between them, because the spread of a 100-nm probe in a section 1 μ m thick is too large compared with the transverse dimensions of the microvilli and the channels. The presence of mitochondria in the microvilli also adds to the scatter in the results. But the observed distributions should be qualitatively valid, and they bear directly on the way in which the movement of water may be coupled to an active movement of ions to maintain near isotonicity of the transported fluids in various animal epithelia. Among several models^{5,12}, the "standing gradient osmotic flow" hypothesis¹⁸ has been applied widely to both vertebrate and invertebrate tissues², but support¹⁸ and criticism^{19,20} of this model have been based on theory alone, in the absence of direct measurements of the gradients. In Malpighian tubules it has been suggested that the cytoplasmic processes in the region of the basal infolds and/or the extracellular spaces between the microvilli in the brush border constitute the forwardly-directed channels in which standing gradients are generated⁸. Our observations show that in *Rhodnius*, transport across the tubule brush border is unlikely to be explained in this way since the direction of the observed gradients is the reverse of that required by the model.

The sum of the Na and K levels in the brush border region is well above the Cl level. This "anion deficit" may

Fig. 3 As Fig. 2, but showing detailed distribution of Na, K and Cl in the microvillar region. The mitochondrion has been omitted from the marked microvilli, for clarity.

be taken as evidence of ion binding to extracellular organic material, possibly the anionic glycocalyx demonstrated by electron microscopy in other tissues^{21,22}.

In the brush border region, we need microanalyses with better spatial resolution, to be obtained with thinner sections of tissue, and we need information about the proportion of ions bound and the amount of free water present. Further experiments are in progress.

In the basal lamina, the high concentrations of potassium have now been found in other insect tissues as well (our unpublished work). The observation cannot be attributed to the limited analytical spatial resolution, which can only tend to obscure existing sharp peaks in concentration. The basal lamina has generally been regarded to be insignificant in relation to fluid transport, as experiments have shown it to be freely permeable to uncharged macromolecules²³ and colloidal particles²⁴. But our results suggest a preferential binding of K by the basal lamina, possibly to anionic sites on collagen or acidic proteoglycans²⁵. The presence of phosphoglycans is suggested by the high concentration of phosphorus, and of anionic sites by the fact that the basal lamina selectively binds lanthanum (unpublished work of B. L. G.). The implication for fluid transport is that the basal lamina, although apparently permeable to quite large neutral molecules, may nevertheless preferentially restrict the movement of some ions. Particularly in the presence of the large net fluxes of ions and water, observed in stimulated Malpighian tubules, the result may be a significant difference in composition between the external medium and that bathing the cells.

Comparison of the biological activities of an insect and a crustacean neurohormone that are structurally similar

THE molecular structure of locust adipokinetic hormone (AKH) (ref. 1), closely resembles that of the only other arthropod neurohormone to be fully characterised, prawn red-pigment-concentrating hormone (RPCH) (ref. 2). The first eight residues of the decapeptide, AKH, are homologous with the octapeptide, RPCH, except for threonine instead of serine as residue 5, and asparagine instead of glycine as residue 7, as shown below.

RPCH: PCA-Leu-Asn-Phe-Ser-Pro-Gly-Trp-NH₂

1 2 3 4 5 6 7 8

AKH: PCA-Leu-Asn-Phe-Thr-Pro-Asn-Trp-Gly-Thr-NH₂

1 2 3 4 5 6 7 8 9 10

Although both hormones are the products of neuroendocrine organs, such close similarities in structure were somewhat unexpected, as the two hormones have completely different physiological actions. AKH in the locust controls lipid utilisation for energy during prolonged flights, by stimulating the release of diglycerides from the fat body³, and regulating their utilisation by the flight muscle⁴. RPCH in the prawn stimulates the concentration of pigment within the red chromatophores⁵. We present here evidence that the two hormones can reproduce each other's effects when cross tested on members of the two arthropod groups.

Earlier work^{6,7} had demonstrated that extracts of corpora cardiaca from several insects were able to concentrate the red chromatophore pigments in prawns and crayfish. In this preliminary study we have investigated the effects on pigment

Fig. 1 Effects of AKH on the chromatophores of *Palaemon squilla*. The prawns were kept in seawater on a black background. Samples of 10 pmol AKH in 10 μ l 2.7% NaCl were injected into six animals; five control animals were not injected but were kept in identical conditions. The average chromatophore indices from groups of 20 chromatophores of each type on the carapace (C), and on the margin of the fifth abdominal sclerite (A) were estimated for each animal, and the results from each animal averaged. Stippled columns, red chromatophores; hatched columns, black chromatophores; open columns, yellow and white chromatophores.

Table 1 Effects of *Dichelopandalus* eyestalk extract and AKH on red chromatophores of *Dichelopandalus bonnierii*

Sample injected	No. of animals	Chromatophore index at various times after injection			
		0 min	20 min	45 min	100 min
Saline	4	4.8	4.9	4.8	4.6
Extract of 0.5 <i>Dichelopandalus</i> eyestalk	5	4.8	1.8		2.8
AKH : 2.0	4	4.8	2.8	1.7	3.8
(pmol) 1.0	4	4.8	Slight effect		
0.2	4	4.9	No effect		

Intact *Dichelopandalus bonnierii* kept in seawater on a red background were injected with 25 μ l 2.7% NaCl in which the test samples were dissolved. Each prawn was approximately 4 g wet weight. The chromatophore indices⁸ for groups of 20 red chromatophores on the carapace and abdomen of each animal were estimated, and the values for each animal averaged. Extracts were prepared, immediately before injection, by disrupting the eyestalks in 2.7% NaCl.

concentration of injecting pure AKH (ref. 1) into different crustacean species. We have also examined the ability of prawn eyestalk extracts to mobilise lipids in locusts. The limited supply of prawns available to us necessitated the use of extracts of eyestalks, rather than pure RPCH.

Table 1 shows the effects on red pigment concentration of injecting both a saline extract of *Dichelopandalus bonnierii* eyestalks, and AKH, into intact *Dichelopandalus*. The prawns were kept on a red background throughout the experiment, so that before injection the red pigment in the chromatophores was fully dispersed. The eyestalk extract and AKH both concentrate the red pigment markedly. Similar blanching effects were observed with methanolic extracts of *Dichelopandalus* eyestalks. When injected with 10 pmol AKH the prawns blanched completely within 5 min, whereas with 2 pmol the maximum effect was observed after 45 min. 1 pmol AKH is required to achieve some blanching in intact *Dichelopandalus*. *Pandalus montagui* also blanched slightly with this level of hormone, though neither species responded to 0.2 pmol AKH. In *Dichelopandalus* with ligatured eyestalks, and thus with the red pigment fully dispersed, three out of five animals blanched slightly with 0.2 pmol AKH; all five animals showed marked blanching 10 min after the injection of 1 pmol AKH. Hence the 'threshold' dose of AKH necessary to achieve an effect in these prawns is between 0.2 and 1 pmol.

The effects on pigment concentration of injecting AKH into

dark-adapted *Palaemon squilla* are illustrated in Fig. 1. Pigment dispersion in the red, black, yellow and white chromatophores of both the carapace and abdomen was measured. 10 pmol AKH concentrated the red and black pigments markedly and had a lesser effect on the yellow and white pigments. The effect was greatest 1 h after injection; after 2.5 h the pigments were fully dispersed again. These results may be compared with earlier studies⁹ on the effects of pure RPCH from *Pandalus borealis* on *Palaemon adspersus* chromatophores. 0.05 pmol RPCH concentrated both red and white pigments though the maximum white chromatophore response was smaller (chromatophore index (CI) 2.5) than the red chromatophore response (CI 1.0).

Dark-adapted *Crangon crangon* injected with 10 pmol AKH became very pale within 5 min of injection. The chromatophore indices of the red and black body chromatophores, and the red chromatophores on the telson, all decreased from CI 4–5 to CI 1.0 in this time and these effects persisted for 45 min. The white and yellow body chromatophores (CI 3.0) were unaffected during this time as were the black chromatophores on the telson (CI 4.5). The dispersions of black pigment in the body and telson are controlled by different factors¹⁰; our findings suggest that AKH is mimicking the body-concentrating factor.

The adipokinetic activities of methanolic extracts of eyestalks from *Dichelopandalus* and *Palaemon* injected into *Locusta migratoria* were measured using the procedure described earlier. The dose-response curves (Fig. 2) demonstrate that both extracts are able to mobilise lipids in locusts. The maximum response elicited by the *Dichelopandalus* extract was lower (11 units per locust) than that produced by the *Palaemon* extract (20 units). The maximum *Palaemon* response is, however, comparable with the maximum response of AKH (20 units per locust)¹.

We have shown that methanolic extracts of *Dichelopandalus*

Fig. 2 Dose-response curves for the adipokinetic activity of methanolic extracts of eyestalks from *Dichelopandalus bonnierii* (a) and *Palaemon squilla* (b). The extracts, redissolved in 20 μ l simple saline were injected into adult male *Locusta migratoria* 19–21 d old and adipokinetic activities were measured as before¹. The results represent the mean activity \pm s.e. from six locusts for the *Dichelopandalus* extract and the mean activity \pm s.e. from four locusts for the *Palaemon* extract.

Table 2 Effects of thermolysin digestion on the adipokinetic activity of AKH and methanolic extracts from *Dichelopandalus* and *Palaemon*

Sample injected	Adipokinetic activity (units) of sample		Comparison of means
	Undigested	Digested with thermolysin	
Simple saline	1.1 \pm 0.7	2.1 \pm 0.4	
5 pmol AKH	19.3 \pm 2.1	2.5 \pm 1.4	$P < 0.001$
Extract from 1.5 <i>Dichelopandalus</i> eyestalks	9.5 \pm 0.4	2.8 \pm 0.4	$P < 0.001$
Extract from 1.5 <i>Palaemon</i> eyestalks	9.1 \pm 0.7	1.8 \pm 0.4	$P < 0.001$

1 nmol AKH, methanolic extracts from eight *Dichelopandalus* eyestalks, and from eight *Palaemon* eyestalks, were each dissolved in 30 μ l 0.067 M NH_4HCO_3 containing 0.15 μ mol CaCl_2 and 0.1 nmol thermolysin. The solutions were incubated for 4 h at 37 $^\circ\text{C}$, heated to 100 $^\circ\text{C}$ for 5 min and NH_4HCO_3 and water removed by lyophilisation. Identical samples, with no enzyme, were treated in the same way. The residues, redissolved in simple saline were assayed for adipokinetic activity¹ in adult male *Locusta* 16–19 d old. The results represent the mean activity \pm s.e. from four locusts.

eyestalks contain a factor with red pigment-concentrating activity. However, to establish whether the lipid-mobilising activity of these extracts is attributable to RPCH, we carried out further experiments. Both AKH¹ and RPCH² are cleaved by thermolysin; this cleavage of AKH destroys all its adipokinetic activity. Table 2 shows that thermolytic digestion of the eyestalk extracts destroys their adipokinetic activities. In addition, both the *Dichelopandalus* and *Palaemon* extracts elicited marked hyperglycaemic activity when injected into cockroaches (W.M. and J.V.S., unpublished) as does AKH (Jones, J. V. S., and W.M., in preparation). From these observations, we can conclude that the factor with adipokinetic activity present in the prawn eyestalk extracts is either RPCH or a peptide which closely resembles RPCH and AKH.

Thus locust AKH can stimulate pigment concentration in prawns and shrimps, and a peptide from crustacean eyestalks, probably RPCH, can mobilise lipids in locusts. As no pure RPCH was available, we were unable to estimate the relative potencies of RPCH and AKH in these two systems. Our findings suggest that these molecules are sufficiently similar in structure to fit on to the hormone receptors in either system; how good each 'fit' is may be indicated by comparing the molar activities of the peptides in each system. We hope to carry out such experiments in the near future.

Up to this point, our detailed knowledge of the comparative endocrinology of arthropods has been restricted to the control of moulting. The moulting hormone, 20-hydroxyecdysone, is of common occurrence in arthropods and acts on the same target, namely the epidermis, in different groups. Our results suggest that the evolution of neurosecretory hormone systems in arthropods is of a different pattern. It seems there has been a similar evolution of hormone structures, but an independent evolution of the target tissues. Examples of structurally similar peptide hormones acting on different targets in different classes are well documented among the vertebrates¹¹.

This work was supported by the SRC. We thank the staff at Millport Marine Biology Station, Isle of Cumbrae, Scotland, for supplying crustaceans and for the use of their laboratory facilities. This work and a previous paper¹ result from collaboration with Dr G. J. Goldsworthy and Dr P. Cheeseman, University of Hull; their participation in the isolation of adipokinetic hormone is acknowledged.

Likely pre-Suez occurrence of a Red Sea fish *Aphanius dispar* in the Mediterranean

THE construction of artificial waterways connecting different faunal provinces provides biologists with an opportunity to observe ecological, biogeographic and evolutionary changes. But recognition of change requires a thorough knowledge of conditions before construction. The opening of the Suez Canal in 1857 is a case in point. More than thirty species of Red Sea fishes have been recorded as

colonising the Mediterranean since the opening of the canal¹, but because no reliable systematic ichthyological collections were made in the eastern Mediterranean before 1857, these new records must be judged with caution. We report here comparative electrophoretic evidence which suggests that the Red Sea cyprinodontid, *Aphanius dispar*, first reported along the Israeli coast in 1947 (ref. 2) and therefore considered a Suez migrant, has been a permanent Mediterranean resident for a long time.

A. dispar (Rüppell) is a small, littoral, euryhaline fish widely distributed in the Indian Ocean, which also occurs along both coasts of the Sinai Peninsula and in the Suez Canal. In the Mediterranean, it was reported at Port Said³ and subsequently along the Israeli coast from Atlit, Tel Aviv, and Caesarea^{2,4}. In addition, several subspecifically distinct populations (*A. dispar richardsoni* (Boulenger)) occur as isolates in freshwater pools along the periphery of the Dead Sea. These Dead Sea fishes have been living in isolation since the early Pleistocene⁵ and differ from conspecifics in male breeding coloration⁶. But all populations of the species have the same gross karyotype, cross freely in aquaria and are morphologically indistinguishable^{6,7}.

We collected population samples of *A. dispar* at five localities from the Mediterranean, Red Sea and Dead Sea (Fig. 1). All specimens were examined for genetic variability at nineteen putative isoenzyme loci by standard methods of starch gel electrophoresis⁸ (Table 1). Genetic similarity between all possible pairs of these populations was calculated by means of Rogers' coefficient (S_R); the values are provided in Table 2.

In general, excluding comparisons between subspecies and karyotypically differentiated populations (which could easily be regarded as sibling species), virtually all intra-specific estimates of genetic similarity (S_R) in a wide variety of organisms have been greater than 0.75^{10,11}. As expected, both population pairs within the Red Sea and Dead Sea exhibit a very high degree of similarity. The estimates of similarity for *A. dispar* between the Mediterranean, Red Sea and Dead Sea are in sharp contrast, however (Table 2). Because *A. dispar* was presumed to have entered the Mediterranean only recently through the Suez Canal^{12,13}, it was expected that this population sample would approximate the level of divergence observed among Red Sea samples. Instead, the degree of difference between Mediterranean and Red Sea samples is as large as that between either sample

Fig. 1 Sampling localities of *Aphanius dispar* in Israel. The scale equals 100 km.

Table 1 Genetic variation at 19 loci in five populations of *A. dispar*

Sample area	Locality	Heterozygosity*	Average no. of alleles per locus	Unique alleles†
Mediterranean	Atlit	6.27	1.26	6
Red Sea	Nabq	2.39	1.37	8
Red Sea	Ras Muhammad	6.00	1.26	
Dead Sea	Ein Fashkha	5.10	1.26	6
Dead Sea	Ein el Ghuweir	4.56	1.11	

Thirty individuals were examined from each locality. With the exception of the assay for lactate dehydrogenase (LDH), all proteins were examined from whole-body homogenates diluted 1:1 with deionised water. LDH was examined from individual homogenates of eye. Electrophoretic procedures and histochemical staining were similar to those described before⁸. Specimens were examined for the following proteins (number of presumed loci in parentheses): esterase (2), LDH (3), malate dehydrogenase (2), phosphoglucosutase (3), isocitrate dehydrogenase (1), general protein (2), α -glycerophosphate dehydrogenase (1), 6-phosphogluconate dehydrogenase (1), phosphoglucose isomerase (2), aldolase (1), and amino peptidase (1).

*Heterozygosity was calculated as the average observed number of heterozygotes per locus, expressed ($\times 100$).

†Unique alleles are those alleles which were observed in only one out of the three sample areas.

and the Dead Sea isolates, whose last conspecific contact was during the early Pleistocene. Such genetic differences are of the order normally associated with interspecific comparisons, where long periods of isolation are indicated¹³. We conclude therefore that *Aphanius dispar* was extant in the Mediterranean before the construction of the Suez Canal.

Our conclusion reinforces speculations about the pre-Suez occurrence of *A. dispar* in the Mediterranean. This species has previously^{14,15} been considered a likely candidate for pre-Suez migration because of its wide salinity tolerance and the high probability of early interoceanic contact facilitated by ancient channelling¹⁶ and eustatic fluctuations.

A. dispar prevented survival in a cooling Mediterranean¹², but measurements of thermal tolerance (our unpublished results) and recent palaeoclimatological estimates of the Pleistocene Mediterranean²⁰ invalidate such concern. There is no support for an extinction of this population. A further argument is by analogy to the occurrence of a congeneric species, *Aphanius fasciatus*. This fish is a widely distributed Mediterranean endemic common in the littoral. After the opening of the Suez Canal, it was reported in abundance from Lake Timsah, 75 km south of the Mediterranean, yet it was formally recorded from the Israeli coast only in 1954¹⁸. Thus, if an ecologically similar and widely distributed Mediterranean resident was not detected along the Israeli

Table 2 Genetic similarity (S_R)⁹ among five Israeli populations of *A. dispar*

	Mediterranean Sea Atlit	Nabq	Red Sea Ras Muhammad	Ein Fashkha	Dead Sea Ein el Ghuweir
Atlit	—	0.721	0.716	0.596	0.580

Ras Muhammad			—	0.731	0.721
Ein Fashkha				—	0.979
Ein el Ghuweir					—

At least two alternative explanations for our observations, consistent with the idea of recent Suez migration, merit attention. First, stochastic events associated with colonisation may have reduced the level of variability and provided a biased sample of founding Red Sea genes. Although a normal level of heterozygosity could easily become re-established if population size increased rapidly, the average number of alleles per locus would recover much more slowly from a severe bottleneck¹⁷. The Mediterranean sample, however, is not distinguished by either homozygosity or a lower average number of alleles compared with conspecifics (Table 1). More convincingly, the presence of unique alleles in all areas sampled (Table 1) can be taken as evidence of substantial isolation and absence of gene flow. Second, the source material for the Mediterranean colonisation may not have come from the Red Sea itself, but from some geographical isolate within the Suez area. For example, the founders could have come from a genetically differentiated population isolated in the Great Bitter Lakes. While this suggestion cannot be excluded, we consider it unlikely (see below).

Several further arguments support our contention that *A. dispar* is of pre-Suez occurrence in the Mediterranean. The progenitors of the Dead Sea subspecies must have colonised the Jordan drainage system from the Mediterranean^{18,19}. The idea that the extant population of *A. dispar* in the Mediterranean is of recent origin is associated with the assumption that the original founding population became extinct. It has been argued that the thermophilic nature of

coast until very recently, what degree of confidence can be placed in early negative reports for *A. dispar*?

Our findings have implications for future oceanic waterways. Clearly, only extremely comprehensive systematic surveys can provide the necessary baselines for evaluating the impact of major faunal interchange. We follow many others^{21,22}, in reiterating this concern with respect to the proposed and much debated sea level canal in Panama.

This research was supported by a grant from the United States-Israel Binational Science Foundation. We thank M. Avrahami, M. Bodmer and W. F. Bodmer for field assistance, N. Nof for translation and M. Goren and U. Ritte for discussion.

Chromosomal recombination and mapping in *Rhizobium leguminosarum*

IGNORANCE of the genetics of the nitrogen-fixing symbiosis between *Rhizobium* species and leguminous plants is due chiefly to the lack of a good system for genetic mapping in *Rhizobium*. Although gene transfer by transformation and transduction have been reported in several *Rhizobium*

species^{1,2}, the only linkage map has come from studies of conjugation in a non-nodulating *R. lupini* strain³ and a genetic analysis of symbiotically defective mutants has not been possible. *R. leguminosarum* is particularly suitable for genetic studies since it nodulates the pea (*Pisum sativum*), a genetically well known legume^{4,5}. Initial studies with many *R. leguminosarum* wild types failed to demonstrate recombination⁶ although P group R factors could be transferred between them^{6,7}. These plasmids have wide host ranges⁸ and have been shown to mediate the transfer of chromosomal genes in *Pseudomonas*⁹, *Escherichia*¹⁰ and *Acinetobacter*¹¹. R68.45 is a derivative of the P group R factor (R68) isolated by Haas and Holloway⁹ for having much better sex factor activity in *P. aeruginosa* than R68 and other R factors. We report here that it behaves in a similar manner in nodulating strains of *R. leguminosarum* and can be used for genetic mapping in this species.

(c) Mapping of mutations by co-transfer percentages

For both crosses the mating mixture was plated undiluted on the four selective media; colony counts on the four media were approximately equal. 150 colonies from cross A and 200 from cross B were picked from each selective medium and characterised for non-selected markers.

We tested RP4, which has been used for conjugation studies in *R. leguminosarum*⁷, R68.44 and R68.45 for their ability to promote recombination in crosses between *R. leguminosarum* strains, using a membrane mating procedure¹². In these crosses equal numbers of donor and recipient bacteria were sucked on to Millipore membranes and incubated overnight on complete medium plates. The bacteria were then washed off in distilled water and between 10⁹ and 10¹⁰ bacteria were plated on each selective medium. The transfer frequencies of RP4, R68.44 and R68.45 (per recipient) were about 10⁻². The R factors were introduced into the *R. leguminosarum* strains by crossing them with appropriate R⁺ *E. coli* donors¹². All *R. leguminosarum* strains were derivatives of the wild-type strain 300¹³ which is able to form normal nitrogen-fixing nodules on the pea (variety Wisconsin Perfection).

RP4 and R68.44 were equally inefficient in promoting chromosome transfer in *R. leguminosarum*. For both, the recombination frequency of approximately 10⁻⁹ per recipient was similar to the reversion rates of the markers being examined and was quite unsuitable for mapping purposes, though a low frequency of true recombination was proved by the recovery of some progeny carrying auxotrophic markers of both parents¹². R68.45 was about 100 times more efficient and crosses using it routinely produced enough recombinants for linkage analysis. Four-factor crosses of the type described by Hopwood^{14,15} for mapping in *Streptomyces* were used because they facilitate recovery of nine of the 16 possible combinations of parental markers by plating on four different selective media and therefore provide a considerable amount of information.

In such crosses, two of which are shown in Table 1a, four of the recovered genotypes differ from one parent or the other by a single marker and the other five differ from both parents by two markers. Of these five, four (the last four in each tabulation) represent two pairs of complementary genotypes. It is clear that: (1) the genotypes differing from

Table 2 Segregation of *rif* and *str*

Cross B	No. of R ⁺ colonies selected on medium containing phenylalanine, cysteine, tryptophan and rifampicin	
<i>ura-14 met-14 rif-74</i> (R68.45)	<i>phe trp rif str</i>	<i>phe trp rif</i>
×	2	65
<i>phe-1 trp-12 str-37</i>		
Cross C	<i>phe cys rif str</i>	<i>phe cys rif</i>
<i>ura-14 met-14 rif-74</i> (R68.45)		
×	2	86
<i>phe-1 cys-7 str-77</i>		

Cross mixtures were plated undiluted and all colonies were picked and characterised for non-selected markers. R⁻ *phe cys str rif* and *phe trp str rif* colonies were assumed to be spontaneous mutants; there were 12 for cross B and none for cross C.

the R⁻ parent by a single marker were much more frequent than those differing from the R⁺ parent by a single marker; (2) one member of each complementary pair of genotypes was much more frequent than the other. Thus we conclude that, as with F⁺ × F⁻ or R⁺ × R⁻ crosses in *E. coli*, transfer was polarised from the plasmid-carrying parent and we can analyse the data for linkage on this assumption. On each plating medium, one donor marker is selected, one is counterselected and the other two are non-selected. The frequencies of the donor non-selected alleles are tabulated (Table 1b). There is no significant transfer of *ser-1*, which is therefore unlinked with the other four; therefore we can analyse their linkage on the media on which *ser-1* is counterselected, without complications due to their possible linkage with the counterselected allele. The other four markers show linkage and the percentage cotransfer frequencies indicate a probable map order *met-14-trp-16-phe-1-ura-14* (Table 1c).

Segregation of *str* and *rif* as non-selected markers in further crosses indicated that neither was closely linked to *ura-14*, *met-14* or *phe-1* and that they appeared to be linked together. A selective analysis of their segregation showed that they were closely linked: selection for transfer of *rif* to the R⁻ parent nearly always led to loss of the recipient *str* marker (Table 2). In *P. aeruginosa*¹⁶, *Bacillus subtilis*¹⁷ and *Streptomyces coelicolor*¹⁸, *rif* and *str* genes are also closely linked; in the latter two organisms rifampicin resistance mutations mapping near *str* have been shown to be in the RNA polymerase gene^{17,18}.

The mutation *trp-16* is closely linked to *phe-1* (Table 1) but *trp-12* showed no linkage with *met-14*, *phe-1* or *ura-14*; this indicates that, unlike *E. coli* or *Bacillus subtilis*, but like *S. coelicolor*¹⁹ and *P. aeruginosa*²⁰, *R. leguminosarum* does not have a single tryptophan operon. This observation is confirmed by data from crosses involving a *R. leguminosarum* donor carrying a derivative of RP4 that mediates the transfer of *trp⁺-14* about 100 times more frequently than RP4 (J.E.B., unpublished results). This donor transfers *trp⁺-14* and *trp⁺-12* at the same high frequency, but *trp⁺-16* at the frequency expected for a wild-type RP4 donor.

In crosses between *P. aeruginosa* strains, R68.45 has multiple sites of origin of chromosome transfer and mobilises fairly short fragments of donor chromosome (about 10–30 min of the *P. aeruginosa* map)⁹. Both these properties of the plasmid seem to apply in *R. leguminosarum* crosses. When selection is for the transfer of markers not showing linkage with *phe-1*, such as *str-37* or *rif-74*, they are found to be transferred as frequently as *phe⁺-1*. Analysis of recombinants shows that, while fairly long fragments can be transferred, most recombinants arise from the inheritance of smaller donor fragments (Table 1). R68.45 transfers at a lower frequency between *R. leguminosarum* strains than between *P. aeruginosa* strains (about 1% and 50% respectively) and this is correlated with the lower frequency of recombination observed in *R. leguminosarum*. But the problem of distinguishing spontaneous revertants from recombinants when analysing progeny on selective media was facilitated by the low frequency of R factor transfer. Spontaneous revertants have a 1% chance of becoming R⁺ and therefore if true recombinants are being formed (for markers with suitably low reversion rates) they should be R⁺. Routinely this was observed; fewer than 5% of colonies on selective media were R⁻.

Why is R68.45 able to mobilise *P. aeruginosa* and *R. leguminosarum* chromosomal genes so efficiently when RP4 and R68.44 are so inefficient in *R. leguminosarum*? RP4 (RP1, R1822)²¹ is a poor sex factor in *P. aeruginosa*⁹ but a good one in *Acinetobacter*¹¹. The donor properties of this plasmid are therefore strain (or species) specific and *R. leguminosarum* strain 300 behaves like *P. aeruginosa* strains PAO and PAT. R68.44 would be expected to behave like R68.45 in *R. leguminosarum*. However R68.44 is an unstable donor in *P. aeruginosa*⁹ and presumably lost this property during its transfer from *P. aeruginosa* to *E. coli* and then to *R. leguminosarum*. R68.44 and a number of similar plasmids were isolated by testing *argB⁺* recombinants in *P. aeruginosa* for enhanced donor activity⁹. The testing of recombinants arising from the transfer of markers from other regions of the chromosome did not yield such donors. Therefore it is likely that R68.44 (and hence R68.45) arose as the result of an interaction between the R factor and *P. aeruginosa* chromosome, rather than the selection of an already existing plasmid mutant. It seems unlikely that R68.45 functions as an improved sex factor in *P. aeruginosa* by virtue of being analogous to an F-prime in *E. coli*. If it were an R-prime it should only have one origin of high frequency transfer in *P. aeruginosa* and would not be expected to function in *R. leguminosarum*. R68.45 also promotes chromosome transfer in *E. coli* K12 strains more

efficiently than R68 (J.E.B. unpublished observations). It seems likely therefore that R68.45 was formed by the pick-up of a *P. aeruginosa* DNA sequence(s) that enables it to interact with the chromosomes of genetically distinct hosts. Insertion sequences are involved in "illegitimate" recombination events^{22,23} and may well be implicated here. Since R68.45 can function as a good sex factor in *R. leguminosarum*, *P. aeruginosa*, *P. putida* and *E. coli* it may be useful in developing genetic studies in other Gram-negative bacteria that are hosts for P group R factors.

We hope that development of the recombination system described here will open the way to a genetic analysis of mutations affecting the nitrogen-fixing symbiosis between *R. leguminosarum* and the pea. It is significant that the majority of the auxotrophic and antibiotic-resistant mutations used as markers did not prevent the formation of effective nodules by multiply marked R⁺ or R⁻ strains (J.E.B., unpublished results) and so should not interfere with the study of relevant mutations.

We thank Shelagh A. Hoggan for technical assistance, Professor P. A. Clarke and B. W. Holloway for *Pseudomonas* strains carrying R68.44 and R68.45, respectively, and Dr A. W. B. Johnston for helpful discussions.

Note added in proof: Since completing this work, we have learnt that Meade and Signer²⁴ have demonstrated linkage between chromosomal genes in *R. meliloti* strain 2011, using RP4 as a sex factor.

Lack of correlation between tight junction morphology and permeability properties in developing choroid plexus

ELECTRON microscopical investigations of tight junctions (zonulae occludentes) using marker substances, have indicated that in some tissues these junctions may represent an extracellular pathway for transepithelial movement of certain small solutes¹ and also restrict the movement of larger solutes². The electrical resistance across some epithelial tissues has been used as a measure of the degree of permeability of the tight junctions to ions³, and it was suggested that junctions that are "leaky" to ions are also leaky

to small non-electrolytes. Examination of tight junctions with the freeze-fracture technique has revealed the presence of a network of intramembranous fibrils⁴ or strands^{5,6}. Some evidence suggests that these strands constitute the sealing component of the junction⁷, and Claude and Goodenough⁸ correlated the transepithelial permeability of a given epithelium with the number of strands in the tight junction network. Artificial methods of altering transepithelial permeability (hypertonic solutions applied to the mucosal side of the epithelium) have been used to investigate changes in transepithelial electrical resistance⁹, and freeze-fracture morphology⁹ or both¹⁰. Results from these studies do not consistently support the above correlation. An alternative approach is described here, in which the freeze-fracture technique has been used to study tight junctions of the sheep choroid plexus during foetal development. The results obtained suggest that there is no change in the ultrastructural features of tight junctions which have previously been suggested to correlate with transepithelial permeability, in spite of considerable changes in permeability during the developmental period studied¹¹⁻¹³.

Fig. 1 Freeze-fracture replicas of a choroid plexus epithelial cell from a, a 40-d and b, a 125-d gestation foetal sheep. a, The fracture has exposed a large area of tight junction towards the apex (cerebrospinal fluid surface) of the cell. There are at least four strands running roughly parallel to the apical cell surface. b, Note the similar number of strands compared with 40-d (a) and that the junctional depth is at least as great at 40-d as at 125-d. Bar indicates 0.5 μ m.

Freeze-fracture replicas were prepared from sheep foetal choroid plexuses at 40, 45, 60 and 125 d of gestation using methods described previously¹⁴. Figure 1a shows a replica of a fracture through the apical region of the choroid plexus epithelium of an early sheep foetus (40 d gestation); it shows the cell membrane faces of adjoining cells. Below the level of the microvilli are seen the linear ridges and complementary linear grooves which constitute the tight junction. Figure 1b shows a replica at 125 d gestation; its appearance is not obviously different from that at 40 d. Similar results were obtained at 45 and 60 d gestation. To test whether permeability of non-electrolytes and establishment of ionic gradients might correlate with strand number and/or junctional depth, detailed studies of a large number of tight junctions at different foetal ages have been carried out (K.M. and N.R.S., unpublished). Measurements of the minimum number of strands and the mean junctional depth were made as described by Claude and Goodenough⁴. Freeze-fracture replicas of more than 400 areas of lateral-apical cell membrane have been examined. Even in the youngest foetuses the choroid plexus intercellular tight junctions contained several continuous strands in all cases. At 40 d gestation the minimum number of strands was 3.64 ± 1.12 and the mean junctional depth was $0.34 \pm 0.17 \mu\text{m}$ (s.d., $n=121$). At 125 d gestation the number of fibrils (3.45 ± 1.13 ; s.d., $n=49$) was not significantly different, but the junctional depth ($0.28 \pm 0.14 \mu\text{m}$; s.d., $n=49$) was significantly less. It has been shown that at these gestational ages, the thin section electron-microscopic appearance of the tight junctions was similar (C. A. N. Evans, D.H.M., K.M., J. M. Reynolds, M. L. Reynolds and N.R.S., unpublished).

Studies of the penetration of materials from blood into brain and cerebrospinal fluid (CSF) in sheep foetuses of the same gestational ages as those examined in the present study have shown considerable changes in the permeability characteristics of the system during foetal development. For example, lipid-insoluble molecules of small molecular weight (erythritol, sucrose and inulin) as well as albumin, penetrate from blood into CSF at a rate and to an extent which may suggest unrestricted passive diffusion at 60 d; in contrast, there is considerable restriction by 125 d, at which stage the mean pore radius was estimated to be about 1 nm (unpublished). Foetal development of CSF-plasma electrolyte gradients has been discussed previously¹¹ and the gradients for individual ions were shown to appear at very different stages in the order magnesium, chloride, potassium, calcium. The concentration of protein in early foetal CSF is very high, for example 500 mg per 100 ml in 55-d sheep foetuses. At least part of this high level seems to be caused by a mechanism which transports specific proteins (for example, α -foetoprotein and transferrin) from blood into CSF early in gestation but not later when the CSF concentration of protein has fallen to near adult levels (50 mg per 100 ml)¹³.

Since tight junction strand number as revealed by freeze fracture does not change significantly during a major part of gestation, this cannot account for the observed alterations in the permeability properties. From the wide variety of epithelia studied with the freeze-fracture technique it is clear that there are important exceptions to the proposed correlation of permeability with fibril (strand) number (ref. 10 and refs therein). Additional evidence against this correlation comes from recent experiments¹⁹ which showed that in the toad bladder treated with hypertonic lysine there was a marked decrease in transepithelial resistance, but no significant change in either fibril number or mean depth of the tight junctions.

It may be that some other feature of tight junctions not revealed by electron microscopy could account for some of these changes in permeability. Both the molecular structure of the junctional membrane and the biochemical composi-

tion of the material enclosed by the junction fibrils might be important for passive ion transport. Nevertheless, one type of extracellular pathway through tight junctions could not account for all our permeability data for the blood-CSF barrier. For example, as mentioned above, there is penetration of albumin from blood into CSF in the 60-d foetus. Such a large pathway, were it present within choroid plexus tight junctions, would be well within the resolution of our electron-microscopical observations. It seems more likely that protein and non-electrolyte penetration and perhaps some type of ion transport involves a quite different route, that is, a transcellular one, consisting of a tubulovesicular system. An intracellular system of tubules and cisternae of endoplasmic reticulum has recently been implicated in transcellular transport of protein¹⁴ and non-electrolytes (C. A. N. Evans, D. H. M., K.M., J. M. Reynolds, M. L. Reynolds and N.R.S., unpublished) in foetal choroid plexus as well as in active sodium transport in frog skin¹⁵.

Errata

The order of the authors of the article "Release and metabolism of substance P in rat hypothalamus" (*Nature*, **264**, 81; 1976) should have been T. Jessell, L. L. Iversen and I. Kanazawa and not as printed.

In the article "Stratospheric aerosols and climatic change" (*Nature*, **263**, 551; 1976) the order of the authors' names was changed and should have read J. B. Pollack, O. B. Toon, A. Summers, B. Baldwin, C. Sagan and W. Van Camp.

In the article "Polymers for the sustained release of proteins and other macromolecules" by R. Langer and J. Folkman (*Nature*, **263**, 797; 1976) the units on the abscissa in Fig. 1 should be hours.

matters arising

A precise definition of chaos

MAY¹ has recently reviewed work on the dynamics of simple recurrence relations. If $x_{n+1} = f(a; x_n)$ where a is a parameter, the system exhibits different behaviours for different values of a . In many cases, there is a range of behaviour characterised by three properties:

- (1) Not all solutions are periodic;
- (2) Asymptotic stability need not obtain;
- (3) Cycles of all periods may occur.

Li and Yorke² show that (1), (2) and (3) necessarily follow if a 3-cycle exists and these authors term such behaviour 'chaotic'. They also show that a 5-cycle may exist without there being a 3-cycle.

The Ukrainian author Sharkovsky³ proves a more general result, which deserves to be more widely known. Let $n_1 < n_2$ if $n_1 \neq n_2$ and the existence of an n_1 -cycle implies the existence of an n_2 -cycle. Sharkovsky shows that

$$\begin{aligned} 3 &< 5 < 7 < 9 < \dots \\ &< 2.3 < 2.5 < 2.7 \dots \\ &< 2^2.3 < 2^2.5 < 2^2.7 < \dots \\ &< 2^3.3 < 2^3.5 < 2^3.7 \\ &< \dots < \dots 2^3 < 2^2 < 2 < 1 \end{aligned} \quad (1)$$

He also demonstrates that there exist recurrence relationships with $(2m+1)$ -cycles but not with $3, 5, \dots, (2m-1)$ -cycles, for any natural number $m = 2, 3, 4, \dots$

In a subsequent paper⁴, Sharkovsky classifies the behaviour of the system in terms of the topological properties of the set C of all points belonging to cycles. If C is a closed set, then all initial values x_0 lead to asymptotically periodic behaviour. This occurs when there are only finitely many cycles (necessarily 2^n -cycles by relation (1)), and in some instances where there are infinitely many cycles all with orders of the form 2^n . If C is not a closed set the number of x_0 not leading to asymptotic periodicity is uncountably large. This occurs whenever there are cycles other than 2^n -cycles and, in some cases, where all the 2^n -cycles occur but only those.

In the first of these instances, requirements (1) and (2) are satisfied, but not necessarily (3). It is not known whether this is true in the second instance, which, however, we conjecture to be structurally unstable to changes in the value of a .

We suggest that requirements (1) and (2) be regarded as defining chaos, but that (3) not be regarded as necessary. This would entail some divergence from the nomenclature of certain authors (for

example, May¹), but it is a consistent convention and one in accord with everyday usage.

A detailed, though still incomplete, list of Sharkovsky's papers is provided by Sibirsky⁵. We also draw attention to the work of Barna⁶, Berg⁷ and Coppel⁸.

We thank Mr W. A. Coppel for his help in supplying some of the reference material. A more complete account of this work will appear elsewhere.

Heat-transfer enhancement with electric fields

CHANGES in heat transfer brought about by electric fields, as reported by Asakawa¹, have been observed for many years. The discovery of the phenomenon is generally attributed to Senftleben and Braun² who observed the systematic enhancement of heat transfer in various gases contained between a cylindrical surface and a coaxial wire when electric fields greater than about 42 kV cm^{-1} were produced at the surface of the wire. The effect was mentioned as early as 1709, however³.

The results reported by Asakawa seem primarily to be the retardation of heat transfer, but in fact seem similar to those expected on the basis of simple inductive heating. It is difficult to quantify heat transfer results with transient experiments, and is generally more informative to rely on steady-state (for example, calorimetric) measurements. Although it is apparently tempting to suggest that the phenomena observed by Asakawa involve material

changes in the material (fluid), there is no evidence for such a conjecture.

We have studied the enhancement of heat transfer in gases by inhomogeneous electric fields in some detail⁴. Our results show that this effect, which, for convenience we call electrocooling, is simply an ionic drag phenomenon (that is, the electric wind of Chattock⁵) in which the convective heat transfer coefficient is proportional to the fourth root of the induced corona current. We derived a theoretical expression which predicts such corona-induced heat transfer within 20% of experimental values for electro-negative gases such as air. As a particular type of forced convection, electrocooling may thus be directly compared to conventional devices such as air jets or blowers.

Scrotal asymmetry and Rodin's dyslexia

MCMANUS¹ has pointed out that most artists depict the left testicle of man lower than the right, in accordance with the facts². An exception occurs in Rodin's famous sculpture *L'Age d'Airan* where the right testicle of the figure seems (from photographs we have seen) to hang lower than the left. We should like to suggest that Rodin was genuinely confused about left and right. Evidence that Rodin suffered from a specific reading disability, which is commonly associated with left-right confusions³, has been reviewed by Thompson⁴. So badly did the artist do in school during his early years that his father was informed: "He is ineducable. The sooner you put him out to work, the better. But I doubt if he can ever make a living."⁵

Some of the facts about scrotal

asymmetry seem themselves rather confused. According to Chang *et al.*², left-handed people may show a reversal of the usual scrotal asymmetry. Cholst⁶, however, maintains that reversal occurs only in the extremely rare condition of *situs inversus totalis*. Chang *et al.* also report that the right testicle is usually heavier than the left, which seems superficially at odds with the observation that the left testicle is lower¹. The generality of this finding should perhaps be checked, in view of the puzzling discrepancy over the relationship to handedness. Nevertheless there is some support for the weight difference described by Chang *et al.* in a recent report that the right human gonad normally develops more rapidly than the left⁷.

We have recently suggested that there is a general tendency for growth gradients to favour the left-hand side^{8,9}. Examples are seen in the temporal planum of the human brain; the habenular nucleus in the brains of amphibia; the control of birdsong by the left hypoglossal nerve; the cervical vertebrae of chickens; the greatly elongated left tooth of the Narwhal; and the left-sided development of the hydrocoel in echinoderms. The concordance among these asymmetries is intriguing, but we are obliged to admit that the faster development of the right gonad in mammals tends to restore parity to the situation.

Rosette formation by human lymphocytes

HANAUMI *et al.*¹ point out the need to elucidate the nature of the receptor for sheep erythrocytes (E) on human T lymphocytes. They have examined the effect of phospholipase A (PLA) on E-rosette formation in a study of

the specificity of the type of lymphocytes involved. They showed that PLA from cobra venom induced the ability to form E rosettes in B-type human peripheral lymphocytes and lymphoid cell lines. In contrast, PLA from bee venom and bovine pancreas were ineffective.

I have used PLA from *Crotalus adamanteus* venom, partially purified on Sephadex G-200 and assayed by a lecithin breakdown test^{2,3}. Incubation of this preparation with human lymphocytes at 37 °C for 1 h resulted in a marked decrease in E-rosette formation. Titration experiments showed that the maximum inhibitory effect was produced with PLA at 1 mg ml⁻¹. The effect of this enzyme preparation was resistant to heating to 100 °C for 10 min, but it was not active at 4 °C. It was non-toxic to human lymphocytes and erythrocytes as measured by release of radioactive chromium. Lymphocytes could recover the ability to form E rosettes ~ 8 h after removal of the enzyme on further incubation at 37 °C. Furthermore, PLA treatment of human spleen membranes released material which could block erythrocytes^{2,3}.

These earlier results conflict with those of Hanaumi *et al.*¹, but the discrepancy may be a result of the different sources of enzyme¹. In addition, Zwaal *et al.*⁴ have shown that PLA purified from cobra venom and bee venom does convert lecithin to lysolecithin, in contrast to that purified from bovine pancreas. They also showed that *in situ* lysolecithin does not cause lysis (of human red cells).

This difference between results is striking. I showed that PLA-treated lymphocytes do not form rosettes, probably because of removal of the E receptors which can be re-expressed by the lymphocytes after removal of the enzyme. This may provide a method of solubilisation of the receptors for chemical characterisation. Hanaumi *et al.* showed however, that the E receptor is resistant to their PLA preparation and suggested that there are E receptors on human B cells which are exposed by PLA, although they were unable to show that neuraminidase treatment unmasked these receptors on B-type lymphoid cell lines, in contrast to peripheral B lymphocytes⁵.

This difference has practical importance for the further study of E receptors.

HANAUMI AND KUMAGAI REPLY—We thank Chapel for her comments¹ on our report concerned with the nature of the receptor for sheep erythrocytes on human lymphocytes and lymphoid cell lines². We too have tested the effect of PLA partially purified from the venom of *Crotalus terrificus*, which is one of the Crotalidae snakes, but not *C. adamanteus* used by Chapel³ on the lymphocytes and lymphoid cell lines. The enzyme preparation (specific activity; 14.7 μmol min⁻¹ mg⁻¹ as assayed using phosphatidylethanolamine from *Escherichia coli*) at 40 μg ml⁻¹ did not induce the ability to form rosettes on lymphoid cell lines. In contrast, incubation of this preparation with human lymphocytes at 37 °C for 30 min showed a marked decrease in E-rosette formation, similar to that observed by Chapel with *C. adamanteus* PLA. Our experiments showed, however, that this treatment simultaneously degrades almost all the receptors for immunoglobulin Fc and complement C3 present on the non-treated lymphocytes and lymphoid cell lines, and also that it strips off the surface immunoglobulins⁴.

In contrast to the Crotalidae enzyme preparation, PLA highly purified from *Naja naja* venom induced the ability to form rosettes, but had no effect on the immunological receptors mentioned above. When the cells treated with PLA, even at concentrations greater than 640 μg ml⁻¹, were incubated at 37 °C in medium containing a foetal calf serum, they grew exponentially at the same rate as did non-treated cells, and the ability to form rosettes disappeared from the cell with time⁵. During these experimental periods no markers other than E receptors changed.

Thus, we agree with Chapel's arguments that among the effects of PLAs from different sources may exist a striking difference which has practical importance for the further study of E receptors. We should emphasise, however, that the PLAs of *Naja naja* and bee venom, though the latter exhibited only a weak activity on the human lymphoid cells, were specifically active in inducing the ability to form rosettes of the cells.

Chemical kaleidoscope

Peter Farago

Memoirs of a Minor Prophet: 70 Years of Organic Chemistry. By Sir Robert Robinson. Pp. viii+252. (Elsevier: Amsterdam, Oxford and New York, 1976.) Dfl.49.50; \$18.95.

I LAST met Sir Robert Robinson a few months before his death in 1975. He looked very old. His sight had become weak and he moved with difficulty. But, sitting behind the big polished desk in his office high above the Thames, he suddenly became animated as he described the research he was still directing. His judgements on people and events showed none of the hazy mellowness to which an 88-year-old is surely entitled.

Robinson has been described by Lord Todd as "one of the few men of science to illumine by their own genius a wide variety of areas in their chosen subject" (*Chem. Brit.*, 11, 296, 1975). Within the international community of chemists, there were, and are, many deeply attracted by Robinson both as a man and as a scientist; yet one must record different reactions also. Nobody working in organic chemistry during the period 1915 to the mid-1950s could remain uninfluenced.

His book is a series of episodic recollections of people, places and scientific work, from early childhood to appointment to the Waynflete Chair of Chemistry at Oxford in 1930. One can compare it to the autobiographical writings of another great chemist, *Aus meinem Leben: von Arbeit, Musse und Freunden*, by Richard Willstätter (edit. by Arthur Stoll, Verlag Chemie, Weinheim, 1949), a tragic and human document about the fate of an outstanding scientist during the cataclysm of 20th century Europe. *Memoirs of a Minor Prophet* does not pretend to those heights because, one suspects, what really interested its author were ideas and things, rather than the human condition. As has been said about one of his great protagonists, he talked to molecules. If he suffered anguish, if he lay awake at night wrestling with the agonies of personal decisions, his book does not tell us about it. Emotions seem to have been fully engaged only with the ideas, substances and practitioners of science.

The autobiography presents a kaleidoscope of chemical ideas and personal views in the context of the first 30

years of this century, when organic chemistry was going through one of its most creative periods. Starting from a comfortable West Country middle-class background, the future Sir Robert passed through a Moravian Church school to Manchester University where H. B. Dixon, a pupil of Vernon Harcourt, was senior professor. Robinson entered the laboratories of W. H. Perkin, Jr, as a research student and started his academic career in the newly established Chair of Pure and Applied Organic Chemistry at Sydney in 1912. In the next 16 years he held five other appointments. Returning to a Chair in Liverpool in 1915, he spent a short, uncomfortable interlude with British Dyes Ltd in Huddersfield, followed by a Chair in St Andrews in 1921.

He returned to Manchester as Professor of Organic Chemistry in 1922 and transferred to University College, London, in 1928. The present book ends on the eve of his departure for Oxford. At each station of his progress there are descriptions of some colleagues and of research work in progress. The point of view is explicitly personal, and not all his contemporaries or those who followed would be expected to agree with it.

This was a most important period not only for science but also for scientists, whose contributions to the social fabric were being generally recognised; but there seem to have been few bridges between the worlds of university, in-

dustry and government the author describes. Of Robinson's contributions both as a theoretician, a practical chemist, and later as an industrial consultant, there can be no doubt. Whatever controversies surrounded some of the theoretical work, whole new fields of organic chemistry were explored by Robinson and his collaborators, laying the groundwork for spectacular insights not only in chemistry but also in many of the life sciences.

There are indications of all these strands in *Memoirs*, but the themes find their context only in terms of the author's personal impressions. Organic chemists will find vignettes of people, occasions and ideas which show the origin of a number of current developments in the science. They might usefully compare their present pre-occupations with those of Robinson's generation, observing carefully not only those ideas treated in the book but those which are absent. For those who are not chemists, the need for highly specialised knowledge of the subject will create a formidable deterrent to understanding. But even for them *Memoirs* does dispose of, yet again, the mythical unemotional scientist, the desiccated calculating engine.

Beautifully produced and not unreasonably priced, the book is utterly disgraced by the lack of subject and topic indices. □

Peter Farago is Editor of Chemistry in Britain.

Diversity of the ecosystem

Ecological Diversity. By E. C. Pielou. (Wiley-International: New York and London, February 1976.) \$16; £8.

It is perhaps idle to speculate on what future generations of ecologists will, with their hindsight, deem to be the important developments of the mid-1970s. One area of ecology, however, that almost certainly will not go unheeded is the complexity-stability problem: not that this is a problem which originated in the mid 1970s but rather that there has been a plethora of approaches to the problem during the past four or five years. The arguments will remain, but one aspect of the problem that has occupied several ecologists is the measurement of the diversity of the ecosystem. Diversity, or complexity, can be measured virtually instantaneously whereas stability, the other side of the problem, can only be measured by observation over a long period of time.

Professor Pielou's book is thus a timely account of the one side of this ecological problem. The introductory chapter includes a brief review of the indices for measuring diversity and

equitability, and stresses particularly the different conceptual treatment of fully censured, as opposed to sampled, communities. The next three chapters provide a useful survey of the models and distributions that have been proposed to account for the number of individuals within the species of a community, and of testing hypotheses about species abundance. Again a distinction is made, being between the type of model based on ecological considerations (for example, the broken stick and niche pre-emption models) and the statistical model (for example, the negative binomial distribution).

The book is concluded with a series of four chapters which could be described as applications and 'odds and ends'. One of these chapters deals with spatial mosaics, with several pages devoted to the use of Markov-type matrices for analysing sequences along a transect, but in an example the categories used are 'bare ground', 'herbs', 'grasses and sedges' and 'tree seedlings', which seem to be a far cry from the precision of the first four chapters. Two other chapters contain a consideration of eight "determinants of diversity"—such factors as the diversity on small islands or the co-existence of potentially competing species. It seems here as if Professor

Pielou is trying to discuss a few areas in which she has personally worked, and thus the coverage of the subject is far from complete (for example, ecological succession is probably one of the more common factors affecting diversity, but this only receives a passing reference in a section dealing with the geological timescale).

Ecologists should take note of this book, particularly as a more rigorous assessment of diversity is likely to be required in approaching the complexity-stability problem. I very much doubt if they will. The extremely mathematical style will put many readers off, which is more the pity since some of the ideas of the last four chapters could usefully be more widely applied and developed. The somewhat obscure style of writing—for example, the third property of diversity indices in section 1.2 which is poorly described—is very frustrating for the reader. But the subject matter shows that there is still a lot of research to do in this field, and I hope the book will point out current deficits in our knowledge.

Xenopus as a model system

From Egg to Adolescent: Xenopus—A Model for Development. By Louie Hamilton. Pp. xi+78. (English Universities Press: London, March 1976.) £3.45.

AMPHIBIANS have long been one of the most popular organisms in embryological laboratories, and in recent years *Xenopus laevis* has become the most widely used amphibian species. Its first important application was in nuclear transplantation, for which it was remarkably, perhaps fortuitously, well adapted. These experiments provided us with the strongest available evidence that all the cells of an organism contain identical genes, and in turn that development involves the continuous regulation of genetic activity. Coming on to the scene as late as it did, it is natural that *Xenopus* has made its main contributions to molecular biology, and to the infant science of molecular embryology. Moreover, certain biologists moved from developmental studies to the chemical dissection of gene structure, without changing their chosen organism. The result is that more is now known about the structure of some genes of *Xenopus* than of any other higher organism.

All of this must colour our expectations in reading Dr Hamilton's book. The reader will find a valuable summary of the main morphological events in the development of *Xenopus*, with very brief references to attempts at analysing these processes. There are many good pictures, especially electron micrographs, but the text suffers in general from a lack of diagrams that would help the reader to follow the complex morphological processes by which the vertebrate body is formed. It is, for example, very difficult to follow the formation of the nervous system in the absence of diagrams.

Nevertheless, the elementary student will find the description of development useful, and from time to time he will find his interest titillated by references to experimental embryology. Sadly, the book will not satisfy any interest it arouses because so few references are given. Surely the corpus of work on *Xenopus* justifies more than thirty-seven references. The molecular aspects of development are combined with nuclear transplantation in a chapter only four pages long, and with only two references. One feels that *Xenopus* deserves a little more! H. R. Woodland

Dr Woodland is a Reader in Animal Development in the Department of Biological Sciences at the University of Warwick, Coventry, UK.

Proteases and biological control

Proteases and Biological Control. (Cold Spring Harbor Conference on Cell Proliferation, Vol. 2.) Edited by E. Reich, D. B. Rifkin and E. Shaw. Pp. x+1021. (Cold Spring Harbor Laboratory: Cold Spring Harbor, New York, 1975.)

THE very many different ways in which proteases contribute to biological control systems is the strongest single impression given by this conference report. Thus, although proteolytic enzymes have been studied for more than three-quarters of a century, it is only recently that it has become apparent how many different control mechanisms depend on these enzymes.

The work of Bayliss and Starling (1902) on the conversion of trypsinogen to trypsin by enterokinase is mentioned as an early example (K. A. Walsh). The first section on structure-function relationships also contains a valuable contribution from H. Neurath on limited proteolysis and zymogen activation. In the report of a meeting devoted to proteases and biological control, it is hardly surprising to find sections on coagulation, complement and kinins, and fibrinolysis. All, however, are excellent and have given the individual contributors the opportunity both to present recent results and to review their special fields.

The more fundamental aspects of protease action are made more comprehensible by a contribution on the specificity of proteinases toward protein substrates (J. S. Fruton). Also contributing towards an understanding of physiological control systems is the section on proteinase inhibitors in which the roles of both α_1 antitrypsin and α_2 macroglobulin are discussed. A number of rather disparate contributions appear in a section entitled Cellular Aspects of Proteinase Action. In one mainly devoted to protein turnover in animal cells, R. T. Schimke raises some fundamental question—such as the reason why proteins undergo continuous degradation *in vivo*. As he points out, a partial answer may be the possibility that about 15% of all proteins contain substitution errors incurred during synthesis. Another important reason for general turnover is also considered, that in its absence, the degradation of particular proteins, needed as part of many physiological changes, would require a set of specific proteinases as numerous as the proteins to be degraded.

A final section on tumour-associated proteinases contains several interesting contributions—for example on plasminogen activators, which are reported

to increase in concentration by a factor of 50 after neoplastic transformation of primary fibroblasts.

In view of the wide coverage, excellent quality of the individual contributions and rapid developments occurring in the field, the book deserves a warm welcome. **A. H. Gordon**

A. H. Gordon is a member of the scientific staff at the National Institute for Medical Research, London, UK.

Ornament of our times

Handbook of Psychopharmacology. Section 1: Neuropharmacology. Edited by Leslie L. Iversen, Susan D. Iversen and Solomon B. Snyder. Vol. 1: Biochemical Principles and Techniques in Neuropharmacology Pp. xiii+298. \$27. Vol. 2: Principles of Receptor Research. Pp. xii+288. \$27. Vol. 3: Biochemistry of Biogenic Amines. Pp. xii+486. \$37. Vol. 4: Amino Acid Neurotransmitters. Pp. xi+317. \$30. Vol. 5: Synaptic Modulators. Pp. xii+381. \$35.40. Vol. 6: Biogenic Amine Receptors. Pp. xii+307. \$30. (Plenum: New York and London, 1975.)

AFTER listening at a Journal Club to a presentation of the latest contribution of Scandinavian psychiatric epidemiology, Sir Aubrey Lewis was once heard to remark that this was not the sort of work which one could criticise, but was an *opus magnum* simply to be admired. The audience was somewhat astonished, never previously having detected any faltering in their professor's critical appetite. After delivering this one line, however, Sir Aubrey proceeded unabashed in his usual sharp and telling style, and everyone was much re-assured.

This set of six books on basic neuropharmacology represents only the first of three runs which will together comprise the complete *Handbook of Psychopharmacology*. We are therefore at this point looking at only part of a very large design. But even at this early stage we must unequivocally welcome the production of an ornament of our times. Here is a work which bears witness to the excitement and distinction of a branch of scientific investigation which has burgeoned over recent years. There is nothing in these books which is plodding or pedestrian, and nothing of the anxious pedantry which is sometimes the stuff of the *Handbook* which is desperately determined to miss nothing. A galaxy of scientists from many countries have contributed. To attempt the usual re-

view summary of contents would inevitably mean such condensation as to be misleading. It is sufficient to say that every important basic scientific aspect of this subject is authoritatively dealt with, and the subject explored out to its frontiers.

So much in essence for Sir Aubrey's opening statement. Following his example, it would however, be churlish not to offer some critical comment on an enterprise so eminently worthy of serious scrutiny. The largest problem which the editors had to face was obviously that of how to order and sort all the various issues, so as to produce a work which served the likely purposes of many different readers. There can be no absolutely satisfactory way of meeting such a sorting problem—to confine the coherence of one set of themes to entire chapters, other themes may inevitably be scattered between volumes. As a sort of test run, it was therefore interesting to look up the entries for phenothiazines in the index of each of these six volumes—no doubt the drug will again be treated in a later psychopharmacology section. What transpires is that in Volume 1 there is discussion of immunochemical assay (which certainly stands by itself). In Volume 2 the drug gets a mention in the EEG Chapter (blocking of dopaminergic transmission), and in the discussion of structure-activity relationships. Influence on 5-hydroxytryptamine and bearing on neuropharmacological theories of schizophrenia comes in Volume 3, whereas in Volume 4 the effect of chlorpromazine on brain GABA levels, and glycine and glutamate uptake, is discussed; and again the blockage of dopamine receptors. In Volume 5, influence of phenothiazines on brain energetics is dealt with (touching again on 5-hydroxytryptamine and dopamine), and later the inhibition of response to norepinephrine. In Volume 6 aspects of the dopamine questions come up once more, and in discussing the structural modification of phenothiazines and related dopamine receptor-blocking, line illustrations have to be produced which hark back to Volume 2.

There might in the next edition be further room for editorial tidying up, but the design of the enterprise in terms of basic science first and clinical application only later, is probably right and inevitable. It is Sir Aubrey's opening statement which stands.

Griffith Edwards

Griffith Edwards is Reader in Drug Dependence in the University of London, and Honorary Director of the Addiction Research Unit, Institute of Psychiatry, London, UK.

Cinnabar elixirs to insulin

Science and Civilisation in China. Vol. 5: Chemistry and Chemical Technology. Part 3: Spagyric Discovery and Invention—Historical Survey from Cinnabar Elixirs to Synthetic Insulin. By Joseph Needham. Pp. xxxv+481: plates 462–476. (Cambridge University: Cambridge and London, May 1976.) £16.

PART 3 of Volume 5 of *Science and Civilization in China* completes the survey of alchemy begun in Part 2 (for review, see *Nature*, **254**, 539, 1975). It is more difficult to read than the earlier part because it analyses in detail material which is quite unlike anything with which the Western historian of science is likely to be familiar. Before Needham and his collaborators have been able to get down to any kind of criticism they have needed to examine the material written in a language which differs from Western languages in its basic make-up. It would be an impertinence on the part of any reviewer who, like myself, does not know Chinese, to make any remark on this subject were it not for one important fact about the book itself. Needham goes to a great deal of trouble skilfully to expound these linguistic difficulties and so makes it clear how he set to work and how he solved his problems. In the course of explaining some of the most recent chemistry he has some striking things to say about the different ways Western terms have been adapted to Chinese. His exposition of the language problem becomes a contribution to the history of chemistry.
